This report provides a description of the programming language X10. X10 is a class-based object-oriented programming language designed for high-performance, high-productivity computing on high-end computers supporting $\approx 10^5$ hardware threads and $\approx 10^{15}$ operations per second.

X10 is based on state-of-the-art object-oriented programming languages and deviates from them only as necessary to support its design goals. The language is intended to have a simple and clear semantics and be readily accessible to mainstream OO programmers. It is intended to support a wide variety of concurrent programming idioms.

The X10 design team consists of David Grove, Ben Herta, Louis Mandel, Josh Milthorpe, Vijay Saraswat, Avraham Shinnar, Mikio Takeuchi, Olivier Tardieu.

For extended discussions and support we would like to thank: Gheorghe Almasi, Robert Blackmore, Rob O’Callahan, Calin Cascaval, Norman Cohen, Elmoootaz Elnozahy, John Field, Kevin Gildea, Sara Salem Hamouda, Michihiro Horie, Arun Iyengar, Chulho Kim, Orren Krieger, Doug Lea, John McCalpin, Paul McKenney, Hiroki Murata, Andrew Myers, Filip Pizlo, Ram Rajamony, R. K. Shyamasundar, V. T. Rajan, Frank Tip, Mandana Vaziri, and Hanhong Xue.

We thank Jonathan Rhees and William Clinger with help in obtaining the \LaTeX style file and macros used in producing the Scheme report, on which this document is based. We acknowledge the influence of the Java\textsuperscript{TM} Language Specification \cite{JavaSpec}, the Scala language specification \cite{ScalaSpec}, and ZPL \cite{ZPL}.
This document specifies the language corresponding to Version 2.6 of the implementation. The redesign and reimplemention of arrays and rails was done by Dave Grove and Olivier Tardieu. Version 1.7 of the report was co-authored by Nathaniel Nystrom. The design of structs in X10 was led by Olivier Tardieu and Nathaniel Nystrom.

Earlier implementations benefited from significant contributions by Raj Barik, Philippe Charles, David Cunningham, Christopher Donawa, Robert Fuhrer, Christian Grothoff, Nathaniel Nystrom, Igor Peshansky, Vijay Saraswat, Vivek Sarkar, Olivier Tardieu, Pradeep Varma, Krishna Nandivada Venkata, and Christoph von Praun. Tong Wen has written many application programs in X10. Guojing Cong has helped in the development of many applications. The implementation of generics in X10 was influenced by the implementation of PolyJ [2] by Andrew Myers and Michael Clarkson.

1 Introduction

Background

The era of the mighty single-processor computer is over. Now, when more computing power is needed, one does not buy a faster uniprocessor—one buys another processor just like those one already has, or another hundred, or another million, and connects them with a high-speed communication network. Or, perhaps, one rents them instead, with a cloud computer. This gives one whatever number of computer cycles that one can desire and afford.

The problem, then, is how to use those computer cycles effectively. One must understand how to divide up the available work into chunks that can be executed simultaneously without introducing undesirable indeterminacy, cycles of “deadly embrace” which jam up processors or causing processors to spin uselessly waiting for conditions that may never materialize.

One response to this problem has been to move to a fragmented memory model. Multiple processors are programmed largely as if they were uniprocessors, but are made to interact via a relatively language-neutral message-passing format such as MPI [12]. This model has enjoyed some success: several high-performance applications have been written in this style. Unfortunately, this model leads to a loss of programmer productivity: the message-passing format is integrated into the host language by means of an application-programming interface (API), the programmer must explicitly represent and manage the interaction between multiple processes and choreograph their data exchange; large data-structures (such as distributed arrays, graphs, hash-tables) that are conceptually unitary must be thought of as fragmented across different nodes; all processors must generally execute the same code in an Single Program Multiple Data (SPMD) fashion etc.

One response to this problem has been the advent of the partitioned global address space (PGAS) model underlying languages such as UPC, Titanium and Co-Array Fortran [3] [16]. These languages permit the programmer to think of a single computation running across multiple processors, sharing a common address space. All data resides at some processor, which is said to have affinity to the data. Each processor may operate directly on the data it contains but must use some indirect mechanism to access or update data at other processors. Some kind of global barriers are used to ensure that processors remain roughly synchronized.
X10 is the first of the second generation of PGAS languages. It is a modern object-oriented programming language that introduces new constructs that significantly simplify scale out programming. The fundamental goal of X10 is to enable scalable, high-performance, high-productivity transformational programming for high-end computers—for traditional numerical computation workloads (such as weather simulation, molecular dynamics, particle transport problems etc) as well as commercial server workloads, such as big data analytics.

X10 is based on state-of-the-art object-oriented programming ideas primarily to take advantage of their proven flexibility and ease-of-use for a wide spectrum of programming problems. X10 takes advantage of several years of research (e.g., in the context of the Java Grande forum, [9, 1]) on how to adapt such languages to the context of high-performance numerical computing. Thus X10 provides support for user-defined struct types (such as Int, Float, Complex etc) and function literals, supports a very flexible form of multi-dimensional arrays (based on ideas in ZPL [4]) and supports IEEE-standard floating point arithmetic. Some capabilities for overloading operator are also provided.

X10 introduces a flexible treatment of concurrency, distribution and locality, within an integrated type system. X10 extends the PGAS model with asynchrony (yielding the APGAS programming model). X10 introduces places as an abstraction for a computational context with a locally synchronous view of shared memory. An X10 computation runs over a large collection of places. Each place hosts some data and runs one or more activities. Activities can be dynamically created. Activities are lightweight threads of execution. An activity may synchronously (and atomically) use one or more memory locations in the place in which it resides, leveraging current symmetric multiprocessor (SMP) technology. A distributed termination construct finish enables code to execute after all activities in the given statement have terminated, thus ensuring that all their side-effects have already taken place. An activity may shift to another place to execute a statement block. X10 provides weaker ordering guarantees for inter-place data access, enabling applications to scale. Multiple memory locations in multiple places cannot be accessed atomically. Immutable data needs no consistency management and may be freely copied by the implementation between places. One or more clocks may be used to order activities running in multiple places. DistArrays, distributed arrays, may be distributed across multiple places and support parallel collective operations. A novel exception flow model ensures that exceptions thrown by asynchronous activities can be caught at a suitable parent activity. Asynchronous initialization of variables is supported. Linking with native code is supported.
2 Overview of X10

X10 is a statically typed object-oriented language, extending a sequential core language with places, activities, clocks, (distributed, multi-dimensional) arrays and struct types. All these changes are motivated by the desire to use the new language for high-end, high-performance, high-productivity computing.

2.1 Object-oriented features

The sequential core of X10 is a container-based object-oriented language similar to Java and C++, and more recent languages such as Scala. Programmers write X10 code by defining containers for data and behavior called classes (§8) and structs (§9), often abstracted as interfaces (§7). X10 provides inheritance and subtyping in fairly traditional ways.

Example:

Normed describes entities with a norm() method. Normed is intended to be used for entities with a position in some coordinate system, and norm() gives the distance between the entity and the origin. A Slider is an object which can be moved around on a line; a PlanePoint is a fixed position in a plane. Both Sliders and PlanePoints have a sensible norm() method, and implement Normed.

interface Normed {
    def norm():Double;
}
class Slider implements Normed {
    var x : Double = 0;
    public def norm() = Math.abs(x);
    public def move(dx:Double) { x += dx; }
}
struct PlanePoint implements Normed {
    val x : Double; val y:Double;
    public def this(x:Double, y:Double) {
        this.x = x; this.y = y;
    }
}
2.1. OBJECT-ORIENTED FEATURES

```java
public def norm() = Math.sqrt(x*x+y*y);
}
```

**Interfaces**  An X10 interface specifies a collection of abstract methods; `Normed` specifies just `norm()`. Classes and structs can be specified to `implement` interfaces, as `Slider` and `PlanePoint` implement `Normed`, and, when they do so, must provide all the methods that the interface demands.

Interfaces are purely abstract. Every value of type `Normed` must be an instance of some class like `Slider` or some struct like `PlanePoint` which implements `Normed`; no value can be `Normed` and nothing else.

**Classes and Structs**  There are two kinds of containers: `classes` (§8) and `structs` (§9). Containers hold data in `fields`, and give concrete implementations of methods, as `Slider` and `PlanePoint` above.

Classes are organized in a single-inheritance tree: a class may have only a single parent class, though it may implement many interfaces and have many subclasses. Classes may have mutable fields, as `Slider` does.

In contrast, structs are headerless values, lacking the internal organs which give objects their intricate behavior. This makes them less powerful than objects (e.g., structs cannot inherit methods, though objects can), but also cheaper (e.g., they can be inlined, and they require less space than objects). Structs are immutable, though their fields may be immutably set to objects which are themselves mutable. They behave like objects in all ways consistent with these limitations; e.g., while they cannot `inherit` methods, they can have them – as `PlanePoint` does.

X10 has no primitive classes per se. However, the standard library `x10.lang` supplies structs and objects `Boolean`, `Byte`, `Short`, `Char`, `Int`, `Long`, `Float`, `Double`, `Complex` and `String`. The user may defined additional arithmetic structs using the facilities of the language.

**Functions.**  X10 provides functions (§10) to allow code to be used as values. Functions are first-class data: they can be stored in lists, passed between activities, and so on. `square`, below, is a function which squares an `Long`. `of4` takes an `Long`-to-`Long` function and applies it to the number 4. So, `fourSquared` computes `of4(square)`, which is `square(4)`, which is 16, in a fairly complicated way.

```scala
val square = (i:Long) => i*i;
val of4 = (f: (Long)=>Long) => f(4);
val fourSquared = of4(square);
```

Functions are used extensively in X10 programs. For example, a common way to construct and initialize an `Rail[Long]` – that is, a fixed-length one-dimensional array of numbers, like an `long[]` in Java – is to pass two arguments to a factory method: the first argument being the length of the rail, and the second being a function which
computes the initial value of the $i^{\text{th}}$ element. The following code constructs a 1-dimensional rail initialized to the squares of 0,1,...,9: $r(0) \equiv 0$, $r(5) \equiv 25$, etc.

```scala
val r : Rail[Long] = new Rail[Long](10, square);
```

**Constrained Types**  X10 containers may declare *properties*, which are fields bound immutably at the creation of the container. The static analysis system understands properties, and can work with them logically.

For example, an implementation of matrices $\text{Mat}$ might have the numbers of rows and columns as properties. A little bit of care in definitions allows the definition of a + operation that works on matrices of the same shape, and * that works on matrices with appropriately matching shapes.

```scala
abstract class Mat(rows:Long, cols:Long) {
  static type Mat(r:Long, c:Long) = Mat{rows==r&&cols==c};
  abstract operator this + (y:Mat(this.rows,this.cols))
    :Mat(this.rows, this.cols);
  abstract operator this * (y:Mat) {this.cols == y.rows}
    :Mat(this.rows, y.cols);
}
```

The following code typechecks (assuming that $\text{makeMat}(m,n)$ is a function which creates an $m \times n$ matrix). However, an attempt to compute $axb_1 + bxc$ or $bxc * axb_1$ would result in a compile-time type error:

```scala
static def example(a:Long, b:Long, c:Long) {
  val axb1 : Mat(a,b) = makeMat(a,b);
  val axb2 : Mat(a,b) = makeMat(a,b);
  val bxc : Mat(b,c) = makeMat(b,c);
  val axc : Mat(a,c) = (axb1 + axb2) * bxc;
  //ERROR: val wrong1 = axb1 + bxc;
  //ERROR: val wrong2 = bxc * axb1;
}
```

The “little bit of care” shows off many of the features of constrained types. The $(\text{rows}:\text{Long}, \text{cols}:\text{Long})$ in the class definition declares two properties, rows and cols.

A constrained type looks like $\text{Mat}(\text{rows==r} \&\& \text{cols==c})$: a type name, followed by a Boolean expression in braces. The type declaration on the second line makes $\text{Mat}(r,c)$ be a synonym for $\text{Mat}(\text{rows==r} \&\& \text{cols==c})$, allowing for compact types in many places.

Functions can return constrained types. The $\text{makeMat}(r,c)$ method returns a $\text{Mat}(r,c)$ – a matrix whose shape is given by the arguments to the method. In particular, constructors can have constrained return types to provide specific information about the constructed values.

---

1 The class is officially declared abstract to allow for multiple implementations, like sparse and band matrices, but in fact is abstract to avoid having to write the actual definitions of + and *.
The arguments of methods can have type constraints as well. The operator $\texttt{this +}$ line lets $A+B$ add two matrices. The type of the second argument $y$ is constrained to have the same number of rows and columns as the first argument $\texttt{this}$. Attempts to add mismatched matrices will be flagged as type errors at compilation.

At times it is more convenient to put the constraint on the method as a whole, as seen in the operator $\texttt{this *}$ line. Unlike for $+$, there is no need to constrain both dimensions; we simply need to check that the columns of the left factor match the rows of the right. This constraint is written in $\{\ldots\}$ after the argument list. The shape of the result is computed from the shapes of the arguments.

And that is all that is necessary for a user-defined class of matrices to have shape-checking for matrix addition and multiplication. The example method compiles under those definitions.

**Generic types** Containers may have type parameters, permitting the definition of generic types. Type parameters may be instantiated by any X10 type. It is thus possible to make a list of integers $\texttt{List[Long]}$, a list of non-zero integers $\texttt{List[Long\{self != 0\}]}$, or a list of people $\texttt{List[Person]}$. In the definition of $\texttt{List}$, $T$ is a type parameter; it can be instantiated with any type.

```java
class List[T] {
  var head: T;
  var tail: List[T];
  def this(h: T, t: List[T]) { head = h; tail = t; }
  def add(x: T) {
    if (this.tail == null)
      this.tail = new List[T](x, null);
    else
      this.tail.add(x);
  }
}
```

The constructor (def $\texttt{this}$) initializes the fields of the new object. The add method appends an element to the list. $\texttt{List}$ is a generic type. When instances of $\texttt{List}$ are allocated, the type parameter $T$ must be bound to a concrete type. $\texttt{List[Long]}$ is the type of lists of element type $\texttt{Long}$, $\texttt{List[List[String]]}$ is the type of lists whose elements are themselves lists of string, and so on.

### 2.2 The sequential core of X10

The sequential aspects of X10 are mostly familiar from C and its progeny. X10 enjoys the familiar control flow constructs: if statements, while loops, for loops, switch statements, throw to raise exceptions and try...catch to handle them, and so on.
X10 has both implicit coercions and explicit conversions, and both can be defined on user-defined types. Explicit conversions are written with the as operation: \( n \text{ as } \text{Long} \). The types can be constrained: \( n \text{ as } \text{Long}\{\text{self } != \emptyset\} \) converts \( n \) to a non-zero integer, and throws a runtime exception if its value as an integer is zero.

### 2.3 Places and activities

The full power of X10 starts to emerge with concurrency. An X10 program is intended to run on a wide range of computers, from uniprocessors to large clusters of parallel processors supporting millions of concurrent operations. To support this scale, X10 introduces the central concept of place (§13). A place can be thought of as a virtual shared-memory multi-processor: a computational unit with a finite (though perhaps changing) number of hardware threads and a bounded amount of shared memory, uniformly accessible by all threads.

An X10 computation acts on \( \text{values} \) through the execution of lightweight threads called \( \text{activities} \). An object has a small, statically fixed set of fields, each of which has a distinct name. A scalar object is located at a single place and stays at that place throughout its lifetime. An aggregate object has many fields (the number may be known only when the object is created), uniformly accessed through an index (e.g., an integer) and may be distributed across many places. The distribution of an aggregate object remains unchanged throughout the computation, thought different aggregates may be distributed differently. Objects are garbage-collected when no longer useable; there are no operations in the language to allow a programmer to explicitly release memory.

X10 has a **unified or global address space**. This means that an activity can reference objects at other places. However, an activity may synchronously access data items only in the current place, the place in which it is running. It may atomically update one or more data items, but only in the current place. If it becomes necessary to read or modify an object at some other place \( q \), the place-shifting operation \( \text{at}(q;F) \) can be used, to move part of the activity to \( q \). \( F \) is a specification of what information will be sent to \( q \) for use by that part of the computation. It is easy to compute across multiple places, but the expensive operations (e.g., those which require communication) are readily visible in the code.

**Atomic blocks.** X10 has a control construct \( \text{atomic } S \) where \( S \) is a statement with certain restrictions. \( S \) will be executed atomically, without interruption by other activities. This is a common primitive used in concurrent algorithms, though rarely provided in this degree of generality by concurrent programming languages.

More powerfully – and more expensively – X10 allows conditional atomic blocks, \( \text{when}(B)S \), which are executed atomically at some point when \( B \) is true. Conditional atomic blocks are one of the strongest primitives used in concurrent algorithms, and one of the least-often available.

2.4. DISTRIBUTED HEAP MANAGEMENT

Asynchronous activities. An asynchronous activity is created by a statement `async S`, which starts up a new activity running `S`. It does not wait for the new activity to finish; there is a separate statement (`finish`) to do that.

2.4 Distributed heap management

X10 is the language for parallel and distributed computing, which is based on the APGAS (Asynchronous Partitioned Global Address Space) programming model. In (A)PGAS, the address space is partitioned into multiple semi-spaces. The semi-space is called `place` in X10. In Managed X10 (X10 on Java VMs), a place is represented as a single Java VM and the semi-space is mapped to the heap of the Java VM.

X10 supports garbage collection. Objects in a local heap (local objects) are collected with (local) garbage collection and there is no way to explicitly free them. The reference to local objects is called `local reference`.

In addition, X10 has another type of reference called `remote reference`. Unlike local reference, remote reference can reference objects at both local and remote places.

With remote reference, an activity (something like thread, it runs on a place at a time but it can move itself to different places) can access objects at a remote place (remote objects) when the activity has moved to the remote place. The place where an object is created is the home place of the object and it does not change for the lifetime.

To guarantee an activity can access remote objects at their home place, the objects with remote reference are protected from (local) garbage collection at their home place even if they have no local reference. Objects can be garbage collected only when they have neither local nor remote reference. The garbage collection that takes care of remote reference is called distributed garbage collection and it is supported in Managed X10.

Distributed garbage collection in Managed X10 [8] tracks the lifetime of remote reference with reference counting. When the local garbage collection at a remote place detects the remote reference is no longer needed at the place, the count is decremented. When the count becomes zero, the local garbage collection at the home place is ready to collect the referenced object in the ordinary way.

This mechanism works in most cases, but when there is unbalance in heap allocation rate between places, there is a risk of out of memory error at a frequently allocating place. This is because remote reference from infrequently allocating (i.e. infrequently garbage collected) places could retain remotely referenced objects longer than needed.

To avoid the out of memory error even with unbalanced heap allocation rate, there is a way to explicitly release remote reference.

A single call of `PlaceLocalHandle.destroy()` (PlaceLocalHandle is an X10 type that bundles multiple remote references to the objects at different places) releases all remote references immediately, thus the local garbage collection at each place becomes ready to collect the referenced object in the ordinary way. It can be called at the point where the all objects referenced by the handle are no longer needed to be accessible with the handle. Local reference to the object at each place won’t be affected.
2.5 Clocks

The MPI style of coordinating the activity of multiple processes with a single barrier is not suitable for the dynamic network of heterogeneous activities in an X10 computation. X10 allows multiple barriers in a form that supports determinate, deadlock-free parallel computation, via the Clock type.

A single Clock represents a computation that occurs in phases. At any given time, an activity is registered with zero or more clocks. The static method Clock.advanceAll tells all of an activity’s registered clocks that the activity has finished the current phase, and causes it to wait for the next phase. Other operations allow waiting on a single clock, starting new clocks or new activities registered on an extant clock, and so on.

Clocks act as barriers for a dynamically varying collection of activities. They generalize the barriers found in MPI style program in that an activity may use multiple clocks simultaneously. Yet programs using clocks properly are guaranteed not to suffer from deadlock.

2.6 Arrays, regions and distributions

X10 provides DistArrays, distributed arrays, which spread data across many places. An underlying Dist object provides the distribution, telling which elements of the DistArray go in which place. Dist uses subsidiary Region objects to abstract over the shape and even the dimensionality of arrays. Specialized X10 control statements such as ateach provide efficient parallel iteration over distributed arrays.

2.7 Annotations

X10 supports annotations on classes and interfaces, methods and constructors, variables, types, expressions and statements. These annotations may be processed by compiler plugins.

2.8 Translating MPI programs to X10

While X10 permits considerably greater flexibility in writing distributed programs and data structures than MPI, it is instructive to examine how to translate MPI programs to X10.

Each separate MPI process can be translated into an X10 place. Async activities may be used to read and write variables located at different processes. A single clock may be used for barrier synchronization between multiple MPI processes. X10 collective operations may be used to implement MPI collective operations. X10 is more general than MPI in (a) not requiring synchronization between two processes in order to
enable one to read and write the other’s values, (b) permitting the use of high-level
atomic blocks within a process to obtain mutual exclusion between multiple activities
running in the same node (c) permitting the use of multiple clocks to combine the ex-
pression of different physics (e.g., computations modeling blood coagulation together
with computations involving the flow of blood), (d) not requiring an SPMD style of computa-

tion.

2.9 Summary and future work

2.9.1 Design for scalability

X10 is designed for scalability, by encouraging working with local data, and limiting
the ability of events at one place to delay those at another. For example, an activity may
atomically access only multiple locations in the current place. Unconditional atomic
blocks are dynamically guaranteed to be non-blocking, and may be implemented using
non-blocking techniques that avoid mutual exclusion bottlenecks. Data-flow synchro-
nization permits point-to-point coordination between reader/writer activities, obviating
the need for barrier-based or lock-based synchronization in many cases.

2.9.2 Design for productivity

X10 is designed for productivity.

Safety and correctness. Programs written in X10 are guaranteed to be statically type
safe, memory safe and pointer safe, with certain exceptions given in §4.13.

Static type safety guarantees that every location contains only values whose dynamic
type agrees with the location’s static type. The compiler allows a choice of how to
handle method calls. In strict mode, method calls are statically checked to be permitted
by the static types of operands. In lax mode, dynamic checks are inserted when calls
may or may not be correct, providing weaker static correctness guarantees but more
programming convenience.

Memory safety guarantees that an object may only access memory within its represen-
tation, and other objects it has a reference to. X10 does not permit pointer arithmetic,
and bound-checks array accesses dynamically if necessary. X10 uses garbage collection
to collect objects no longer referenced by any activity. X10 guarantees that no
object can retain a reference to an object whose memory has been reclaimed. Further,
X10 guarantees that every location is initialized at run time before it is read, and every
value read from a word of memory has previously been written into that word.

X10 programs that use only the common, specified clock idioms and unconditional
atomic blocks are guaranteed not to deadlock. Unconditional atomic blocks are non-
blocking, hence cannot introduce deadlocks. Many concurrent programs can be shown
to be determinate (hence race-free) statically.
Integration. A key issue for any new programming language is how well it can be integrated with existing (external) languages, system environments, libraries and tools. We believe that X10, like Java, will be able to support a large number of libraries and tools. An area where we expect future versions of X10 to improve on Java like languages is *native integration* (§18). Specifically, X10 will permit multi-dimensional local arrays to be operated on natively by native code.

2.9.3 Conclusion

X10 is considerably higher-level than thread-based languages in that it supports dynamically spawning lightweight activities, the use of atomic operations for mutual exclusion, and the use of clocks for repeated quiescence detection.

Yet it is much more concrete than languages like HPF in that it forces the programmer to explicitly deal with distribution of data objects. In this the language reflects the designers’ belief that issues of locality and distribution cannot be hidden from the programmer of high-performance code in high-end computing. A performance model that distinguishes between computation and communication must be made explicit and transparent. At the same time we believe that the place-based type system and support for generic programming will allow the X10 programmer to be highly productive; many of the tedious details of distribution-specific code can be handled in a generic fashion.

---

2In this X10 is similar to more modern languages such as ZPL [4].
3 Lexical and Grammatical structure

Lexically a program consists of a stream of white space, comments, identifiers, keywords, literals, separators and operators, all of them composed of Unicode characters in the UTF-8 (or US-ASCII) encoding.

3.1 Whitespace

ASCII space, horizontal tab (HT), form feed (FF) and line terminators constitute white space.

3.2 Comments

All text included within the ASCII characters “/*” and “*/” is considered a comment and ignored; nested comments are not allowed. All text from the ASCII characters “//” to the end of line is considered a comment and is ignored.

3.3 Identifiers

Identifiers consist of a single letter followed by zero or more letters or digits. The letters are the ASCII characters a through z, A through Z, and __. Digits are defined as the ASCII characters 0 through 9. Case is significant; a and A are distinct identifiers, as is a keyword, but As and AS are identifiers. (However, case is insignificant in the hexadecimal numbers, exponent markers, and type-tags of numeric literals – 0xbabe = 0XBABE.)

In addition, any string of characters may be enclosed in backquotes ‘ to form an identifier – though the backquote character itself, and the backslash character, must be quoted by a backslash if they are to be included. This allows, for example, keywords to be used as identifiers. The following are backquoted identifiers:
```
'while', '!', '{unbalanced(', '\', '0'

Certain back ends and compilation options do not support all choices of identifier.

### 3.4 Keywords

X10 uses the following keywords:

```plaintext
abstract as assert async at 
athome ateach atomic break case 
catch class clocked continue def 
default do else extends false 
final finally finish for goto 
haszero here if implements import 
in instanceof interface native new 
null offer offers operator package 
private property protected public return 
self static struct super switch 
this throw transient true try 
type val var void when 
while
```

Keywords may be used as identifiers by enclosing them in backquotes: `new` is an identifier, new is a keyword but not an identifier.

Note that the primitive type names are not considered keywords.

### 3.5 Literals

Briefly, X10 v2.4 uses fairly standard syntax for its literals: integers, unsigned integers, floating point numbers, booleans, characters, strings, and null. The most exotic points are (1) unsigned numbers are marked by a `u` and cannot have a sign; (2) `true` and `false` are the literals for the booleans; and (3) floating point numbers are `Double` unless marked with an `f` for `Float`.

Less briefly, we use the following abbreviations:

- `d` = one or more decimal digits only starting with 0 if it is 0
- `d_8` = one or more octal digits
- `d_16` = one or more hexadecimal digits, using a-f or A-F for 10-15
- `i` = `d | 0d_8 | 0x(d_16 | 0Xd_16`
- `s` = optional `+` or `-`
- `b` = `d | d.d | .d`
- `x` = `(e | E)sd`
- `f` = `bx`

- true and false are the Boolean literals.
null is a literal for the null value. It has type Any{self==null}.

Int literals have the form sin or siN. E.g., 123n, -321N are decimal Ints, 0123N and -0321N are octal Ints, and 0x123n, -0X321N, 0xBEDN, and 0xBEBCN are hexadecimal Ints.

Long literals have the form si, siL. E.g., 1234567890 and 0xBABEL are Long literals.

UInt literals have the form iun or iu, or capital versions of those. E.g., 123un, 0123un, and 0xBEAUN are UInt literals.

ULong literals have the form iu, iul or i, or capital versions of those. For example, 123u, 0124567012u, 0xBaefu, and 0xBEAUN are ULong literals.

Short literals have the form sis or siS. E.g., 414S, OxACES and 7001s are short literals.

UShort literals form ius or iu, or capital versions of those. For example, 609US, 107us, and 0xBEAUS are unsigned short literals.

Byte literals have the form sib or sib. (The letter B cannot be used for bytes, as it is a hexadecimal digit.) 50Y and 0xBABY are byte literals.

UByte literals have the form iyu or iu, or capitalized versions of those. For example, 9uy and 0xBEUY are UByte literals.

Float literals have the form sff or sF. Note that the floating-point marker letter f is required: unmarked floating-point-looking literals are Double. E.g., 1f, 6.023E+32f, 6.626068E-34F are Float literals.

Double literals have the form sf1s/f, and sfd. E.g., .0, .0e100, 1.3D, 229792458d, and 314159265e-8 are Double literals.

Char literals have one of the following forms:

- 'c' where c is any printing ASCII character other than \ or ', representing the character c itself; e.g., "'!';
- '\b', representing backspace;
- '\t', representing tab;
- '\n', representing newline;
- '\f', representing form feed;
- '\r', representing return;
- '\', representing single-quote;

1Except that literals like 1 which match both i and f are counted as integers, not Double; Doubles require a decimal point, an exponent, or the d marker.
• String literals consist of a double-quote ", followed by zero or more of the contents of a Char literal, followed by another double quote. E.g., "hi!", "".

3.6 Separators

X10 has the following separators and delimiters:

( ) { } [ ] ; , .

3.7 Operators

X10 has the following operator, type constructor, and miscellaneous symbols. (? and : comprise a single ternary operator, but are written separately.)

== != < > <= >=
&& || & | ^
<< >> >>>
+ - * / %
++ -- ! -
&= |= ^=
<= >= >>>=
+= -= *= /= %=
= ? : => ->
:< ::= @ ..
** !* -= < >-

The precedence of the operators is as follows. Earlier rows of the table have higher precedence than later rows, binding more tightly. For example, a+b*c<d parses as (a+(b*c))<d, and -1 as Byte parses as -(1 as Byte).
3.8 Grammatical Notation

In this manual, ordinary BNF notation is used to specify grammatical constructions, with a few minor extensions. Grammatical rules look like this:

Adj ::= Adv? happy
     |    Adv? sad

Adv ::= very
     |    Adv Adv

Terms in italics are called non-terminals. They represent kinds of phrases; for example, ForStmt [20.74] describes all for statements. Equation numbers refer to the full X10 grammar, in §20. The small example has two non-terminals, Adv and Adj.

Terms in fixed-width font are terminals. They represent the words and symbols of the language itself. In X10, the terminals are the words described in this chapter.

A single grammatical rule has the form A ::= X₁ X₂...Xₙ, where the Xᵢ’s are either terminals or nonterminals. This indicates that the non-terminal A could be an instance of X₁, followed by an instance of X₂, ..., followed by an instance of Xₙ. Multiple rules for the same A are allowed, giving several possible phrasings of A’s. For brevity, two rules with the same left-hand side are written with the left-hand side appearing once, and the right-hand sides separated by |.

In the Adj example, there are two rules for Adv, Adv ::= very and Adv ::= Adv Adv. So, an adverb could be very, or (by three uses of the rule) very very, or, one or more verys.

The notation A² indicates an optional A. This is an ordinary non-terminal, defined by the rules:

²Grammar rules are given in §20 and referred to by equation number in that section.
The first rule says that \( A^2 \) can amount to nothing; the second, that it can amount to an \( A \). This concept shows up so often that it is worth having a separate notation for it. In the \( Adj \) example, an adjective phrase may be preceded by an optional adverb. Thus, it may be happy, or very happy, or very very sad, etc.
4 Types

X10 is a strongly typed object-oriented language: every variable and expression has a type that is known at compile-time. Types limit the values that variables can hold.

X10 supports four kinds of values, objects, struct values, functions, and null. Objects are in the grand tradition of object-oriented languages, and the heart of most X10 computations. They are instances of classes (§8); they hold zero or more data fields that may be mutable. They respond to methods, and can inherit behavior from their superclass.

Struct values are similar to objects, though more restricted in ways that make them more efficient in space and time. Their fields cannot be mutable, and, although they respond to methods, they do not inherit behavior. They are instances of struct types (§9).

Together, objects and struct values are called containers, because they hold data.

Functions, called closures, lambda-expressions, and blocks in other languages, are instances of function types (§10). A function has zero or more formal parameters (or arguments) and a body, which is an expression that can reference the formal parameters and also other variables in the surrounding block. For instance, (x:Long)=>x*y is a unary integer function which multiplies its argument by the variable y from the surrounding block. Functions may be freely copied from place to place and may be repeatedly applied.

Finally, null is a constant, often found as the default value of variables of object type. While it is not an object, it may be stored in variables of class type – except for types which have a constraint (§4.5) which specifically excludes null.

These runtime values are classified by types. Types are used in variable declarations (§12.2), coercions and explicit conversions (§11.9.1), object creation (§11.21), static state and method accessors (§11.4), generic classes, structs, interfaces, and methods (§4.3), type definitions (§4.4), closures (§10), class, struct, and interface declarations (§8.1.2), subtyping expressions (§11.25), and instanceof and as expressions (§11.24).

The basic relationship between values and types is the is a value in relation: e is a value in T. We also often say “e has type T” or “e is an element of type T”. For example, 1 has type Long (the type of all integers representible in 64 bits). It has the more general
type Any (since all entities have type Any). Furthermore, it has such types as “Nonzero integer” and “Integer equal to one”, and many others. These types are expressable in X10 using constrained types (§4.5). Long{self!=0} is the type of Longs which are not equal to zero, and Long{self==1} is the type of the Longs which are equal to one.

The basic relationship between types is subtyping: T <: U holds if every value in T is also a value in U. Two important kinds of subtyping are subclassing and strengthening. Subclassing is a familiar notion from object-oriented programming. Here we use it to refer to the relationship between a class and another class it extends or an interface it implements. For instance, in a class hierarchy with classes Animal and Cat such that Cat extends Mammal and Mammal extends Animal, every instance of Cat is by definition an instance of Animal (and Mammal). We say that Cat is a subclass of Animal, or Cat <: Animal by subclassing. If Animal implements Thing, then Cat also implements Thing, and we say Cat <: Thing by subclassing.

Strengthening is an equally familiar notion from logic. The instances of Long{self == 1} are all elements of Long{self != 0} as well, because self == 1 logically implies self != 0; so Long{self == 1} <: Long{self !=0} by strengthening. X10 uses both notions of subtyping. See §4.9 for the full definition of subtyping in X10.

4.1 Type System

X10 has several sorts of types. In this section, S, T, and T1 range over types. X ranges over type variables, M and x, over identifiers, c over constraint expressions (§4.5), and e, over expressions. For compactness, slanted brackets are used to indicate optional elements.

\[
\begin{align*}
\text{Type} & := T \\
T & := M \\
| X \\
| M \ [T_1, \ldots, T_n] \\
| T_1 . T_2 \\
| F \\
| M /[T_1, \ldots, T_n] \ (e_1, \ldots, e_k) \\
| T\{c\} \\
F & := (\ [x_1 : T_1, \ldots, x_n : T_n] \ {c} \ } => T \\
| (\ [x_1 : T_1, \ldots, x_n : T_n] \ {c} \ } => \text{void}
\end{align*}
\]

A type given by (1) is an identifier M, like Point, Long, or long. It refers to a unit – a class, struct type, or interface, (§4.2). Or, it can refer to a name defined by a type statement (§4.4).

1X10 automatically uses the identifier self for the element of the type being constrained.

2The actual grammar, as given in §20, is slightly more intricate for technical reasons. The set of types is the same, however, and this grammar is better for exposition.
Example: **String** refers to the standard class of strings, **Long** to the standard struct type of integers, and **Any** to the interface that describes all X10 values. **long** is an alias for the type **Long**, for the comfort of programmers used to other languages in the C family.

A type of the form (2), a type variable **X**, refers to a parameter type of a generic (parameterized) type, as described in §4.3.

**Example:** The class **Pair[X]** below provides a simplistic way to keep two things of the same type together. **Pair[Long]** holds two integers; **Pair[Pair[String]]** holds two pairs of strings. Within the definition of **Pair**, the type variable **X** is the parameter type of **Pair** – that is, the type which this pair is a pair of.

```java
class Pair[X] {
    public val first : X;
    public val second: X;
    public def this(f:X, s:X) {first = f; second = s;}
}
```

A type of form (3), **M[T,U]**, is a use of a generic type, also described in §4.3 or a generic type-defined type without value parameters (§4.4). The types inside the brackets are the actual parameters corresponding to the formal parameters of the parameterized type **M**. **Pair[Long]**, above, is an example of a use of the generic type **Pair**.

A type of form (4), **T.U**, is a qualified type: a unit **U** appearing inside of the unit **T**, as described in §8.14.

**Example:**
```java
class Outer {
    class Inner { /* ... */ }
}
```

then (new Outer()).new Inner() creates a value of type **Outer.Inner**.

A type of form (5), **F**, such as **(x:Long)=>Long**, is a function type. Its values are functions, e.g., the squaring function taking integers to integers. Function types are described in §4.6 and computing with functions is described in §10.

**Example:** **square** is the squaring function on integers. It is used in the assert line.

```java
val square : (x:Long)=>Long
    = (x:Long)=>x*x;
assert square(5) == 25;
```

A term of form (6), such as **M[T](e)**, is an instance of a parameterized type definition. Such types may be parameterized by both types and values. This is described in §4.4.

**Example:** **Array[Long](1)** is the type of one-dimensional arrays of integers. It has one type parameter giving the type of element, here **Long**. It has one value parameter.

---

3In practice, most people would use an **Array** rather than making a new **Pair** class.
CHAPTER 4. TYPES

giving the number of dimensions, here 1. Region(1) is the type of one-dimensional regions of points ([16.4.1]).

In the function types (6), the variable names are bound. As with all bound variables in X10, they can be renamed. So, for example, the types \( (x:\text{Long}) \Rightarrow \text{Long}\{\text{self}\neq x\} \) and \( (y:\text{Long}) \Rightarrow \text{Long}\{\text{self}\neq y\} \) are equivalent, as they differ by nothing but the names of bound variables. This is more visible with types than with, say, methods or functions, because we can test equality of types.

Furthermore, if a variable \( x \) does not appear anywhere in a function type \( F \) save as an argument name, it (and its “:”) can be omitted. E.g., the types \( (x:\text{Long}) \Rightarrow \text{Long} \) and \( (\text{Long}) \Rightarrow \text{Long} \) are equivalent.

Example:

\[
\begin{align*}
\text{val } f : (x:\text{Long}) & \Rightarrow \text{Long}\{\text{self}\neq x\} = (x:\text{Long}) \Rightarrow (x+1) \text{ as Long}\{\text{self}\neq x\}; \\
\text{val } g : (y:\text{Long}) & \Rightarrow \text{Long}\{\text{self}\neq y\} = f; \\
\text{val } t : (x:\text{Long}) & \Rightarrow \text{Long} = (x:\text{Long}) \Rightarrow x; \\
\text{val } u : (\text{Long}) & \Rightarrow \text{Long} = t;
\end{align*}
\]

A term of form (7), \( T\{c\} \), is a type whose values are the values of type \( T \) for which the constraint \( c \) is true. This is described in §4.5.

Example: A variable of class \( \text{Point} \), unconstrained, can contain null:

\[
\begin{align*}
\text{var } \text{gotNPE} : \text{Boolean} & = \text{false}; \\
\text{val } p : \text{Point} & = \text{null}; \\
\text{try } \{ \\
\text{val } q = p * 2; \quad \text{// method invocation, NPE} \\
\} \\
\text{catch}(\text{NullPointerException}) & \{ \\
\text{gotNPE} = \text{true}; \\
\} \\
\text{assert } \text{gotNPE};
\end{align*}
\]

A suitable constraint on that type will prevent a null from ever being assigned to the variable. The variable \( \text{self} \), in a constraint, refers to the value being constrained, so the constraint \( \text{self} \neq \text{null} \) means “which is not null”. So, adding a \( \{\text{self} \neq \text{null}\} \) constraint to \( \text{Point} \) results in a compile-time error, rather than a runtime null pointer exception.

\[
\begin{align*}
\text{// ERROR: } p : \text{Point}\{\text{self} \neq \text{null}\} & = \text{null};
\end{align*}
\]

4.2 Unit Types: Classes, Struct Types, and Interfaces

Most X10 computation manipulates values via the unit types: classes, struct types, and interfaces. These types share a great deal of structure, though there are important differences.
4.2. UNIT TYPES: CLASSES, STRUCT TYPES, AND INTERFACES

4.2.1 Class types

A class declaration declares a class type (§8), giving its name, behavior, and data. It may inherit from zero or one parent class. It may also implement zero or more interfaces, each one of which becomes a supertype of it.

Example: The Position class below could describe the position of a slider control. The example method uses Position as a type. Position is a subtype of the type Poser.

```java
interface Poser {
    def pos():Long;
}
class Position implements Poser {
    private var x : Long = 0;
    public def move(dx:Long) { x += dx; }
    public def pos() : Long = x;
    static def example() {
        var p : Position;
    }
}
```

The null value, represented by the literal null, is a value of every class type C. The type whose values are all instances of C except null can be defined as C{self != null}.

4.2.2 Struct Types

A struct declaration (§9) introduces a struct type containing all instances of the struct. Struct types can include nearly all the features that classes have. They can implement interfaces, which become their supertypes just as for classes; but they do not have superclasses, and cannot extend anything.

Example: The Coords struct gives an immutable position in 3-space. It is used as a type in example():

```java
struct Position {
    public val x:Double; public val y:Double; public val z:Double;
    def this(x:Double, y:Double, z:Double) {
        this.x = x; this.y = y; this.z = z;
    }
    static def example(p: Position, q: Rail[Position]) {
        var r : Position = p;
    }
}
```
4.2.3 Interface types

An interface declaration (§7) defines an interface type, specifying a set of instance method signatures and property method signatures which must be provided by any container declared to implement the interface. They can also declare static val fields, which are provided to all units implementing or extending the interface. They do not have code, and cannot implement anything. An interface may extend multiple interfaces. Each interface it extends becomes one of its superclasses.

Example: Named and Mobile are interfaces, each specifying a single method. Person and NamedPoint are subtypes of both of them. They are used as types in the example method.

```scala
interface Named {
    def name():String;
}
interface Mobile {
    def where():Long;
    def move(howFar:Long):void;
}
interface NamedPoint extends Named, Mobile {}
class Person implements Named, Mobile {
    var name:String; var pos: Long;
    public def name() = this.name;
    public def move(howFar:Long) { pos += howFar; }
    public def where() = this.pos;
    public def example(putAt:Mobile) {
        this.pos = putAt.where();
    }
}
```

4.2.4 Properties

Classes, interfaces, and structs may have properties, specified in parentheses after the type name. Properties are much like public val instance fields. They have certain restrictions on their use, however, which allows the compiler to understand them much better than other public val fields. In particular, they can be used in types. E.g., the number of elements in a rail is a property of the rail, and an X10 program can specify that two rails have the same number of elements.

Example: The following code declares a class named Coords with properties x and y and a move method. The properties are bound using the property statement in the constructor.

```scala
class Coords(x: Long, y: Long) {
    def this(x: Long, y: Long) :
        Coords{self.x=x, self.y=y} {
```
4.3. TYPE PARAMETERS AND GENERIC TYPES

A class, interface, method, or type definition may have type parameters. Type parameters can be used as types, and will be bound to types on instantiation. For example, a generic stack class may be defined as Stack[T] {...}. Stacks can hold values of any type; e.g., Stack[Long] is a stack of longs, and Stack[Point {self!=null}] is a stack of non-null Points. Generics must be instantiated when they are used: Stack, by itself, is not a valid type. Type parameters may be constrained by a guard on the declaration (§4.4, §8.4.6, §10.3).

A generic class (or struct, interface, or type definition) is a class (resp. struct, interface, or type definition) declared with $k \geq 1$ type parameters. A generic class (or struct, interface, or type definition) can be used to form a type by supplying $k$ types as type arguments within [...].

Example: Bottle[T] is a generic class. A Bottle[T] can hold a value of type T; the variable yup in example() is of type Bottle[Boolean] and thus can hold a Boolean. However, Bottle alone is not a type.

```java
class Bottle[T] {
    var contents : T;
    public def this(t:T) { contents = t; }
    public def putIn(t:T) { contents = t; }
    public def get() = contents;
    static def example() {
        val yup : Bottle[Boolean] = new Bottle[Boolean](true);
        //ERROR: var nope : Bottle = null;
    }
}
```

A class (whether generic or not) may have generic methods.

Example: NonGeneric has a generic method first[T](x:List[T]). An invocation of such a method may supply the type parameters explicitly (e.g., first[Long](z)).

---

4By contrast, in Java, the equivalent of Bottle alone would be a type, via type erasure of generics.
In certain cases (e.g., `first(z)`), type parameters may be omitted and are inferred by the compiler (§4.12).

```scala
class NonGeneric {
  static def first[T](x:List[T]):T = x(0);
  def m(z:List[Long]) {
    val f = first[Long](z);
    val g = first(z);
    return f == g;
  }
}
```

**Limitation:** X10 v2.4’s C++ back end requires generic methods to be static or final; the Java back end can accommodate generic instance methods as well.

### 4.4 Type definitions

A type definition can be thought of as a type-valued function, mapping type parameters and value parameters to a concrete type.

```latex
TypeDefDecln ::= Mods? type Id TypeParams? Guard? = Type ;
| Mods? type Id TypeParams? (FormalList ) Guard? = Type ;
TypeParams ::= [ TypeParamList ]
Formals ::= (FormalList? )
Guard ::= DepParams
```

During type-checking the compiler replaces the use of such a defined type with its body, substituting the actual type and value parameters in the call for the formals. This replacement is performed recursively until the type no longer contains a defined type or a predetermined compiler limit is reached (in which case the compiler declares an error). Thus, recursive type definitions are not permitted.

Type definitions are considered applicative and not generative – they do not define new types, only aliases for existing types.

Type definitions may have guards: an invocation of a type definition is illegal unless the guard is satisfied when formal types and values are replaced by the actual parameters.

Type definitions may be overloaded: two type definitions with the same name are permitted provided that they have a different number of type parameters or different number or type of value parameters. The rules for type definition resolution are identical to those for method resolution.

However, `T()` is not allowed. If there is an argument list, it must be nonempty. This avoids a possible confusion between `type T = ...` and `type T() = ...`.

A type definition for a type `T` can appear:

- As a top-level definition in a file named `T.x10`; or
4.4. TYPE DEFINITIONS

- As a static member in a container definition; or
- In a block statement.

Use of type definitions in constructor invocations If a type definition has no type parameters and no value parameters and is an alias for a container type, a new expression may be used to create an instance of the class using the type definition’s name. Similarly, a parameterless alias for an interface can be used to construct an instance of an anonymous class. Given the following type definition:

\[
\text{type } A = C[T_1, \ldots, T_k]\{c\};
\]

where \(C[T_1, \ldots, T_k]\) is a class type, a constructor of \(C\) may be invoked with \(\text{new } A(e_1, \ldots, e_n)\), if the invocation \(\text{new } C[T_1, \ldots, T_k](e_1, \ldots, e_n)\) is legal and if the constructor return type is a subtype of \(A\).

Example: The names of the class \(\text{Cont}[X]\) and the interface \(\text{Inte}[X]\) can be used to create an object \(a\) of type \(\text{Cont}[\text{Long}]\), and an object \(b\) which implements \(\text{Inte}[\text{Long}]\). The two types may be given aliases \(A\) and \(B\), which may then be used in more compact expressions to construct objects \(aa\) and \(bb\) of the same types.

```scala
class ConstructorExample {
  static class Cont[X]{}
  static interface Inte[X]{
    def meth():X;
  }
  public static def example() {
    val a = new Cont[Long]();
    val b = new Inte[Long](){public def meth()=3;};
    type A = Cont[Long];
    val aa = new A();
    type B = Inte[Long];
    val bb = new B(){public def meth()=4;};
  }
}
```

Automatically imported type definitions The collection of type definitions in `x10.lang._` is automatically imported in every compilation unit.

4.4.1 Motivation and use

The primary purpose of type definitions is to provide a succinct, meaningful name for complex types and combinations of types. With value arguments, type arguments, and constraints, the syntax for X10 types can often be verbose. For example, a non-null list of non-null strings is

\[
\text{List[String{self!=null}]{self!=null}}
\]
We could name that type:

```java
static type LnSn = List[String{self!=null}]{self!=null};
```

Or, we could abstract it somewhat, defining a type constructor `Nonnull[T]` for the type of `T`'s which are not null:

```java
class Example {
    static type Nonnull[T]{T isref} = T{self!=null};
    var example : Nonnull[Example] = new Example();
}
```

Type definitions can also refer to values, in particular, inside constraints. The type of `n`-element `Array[Long](1)` is `x10.regionarray.Array[Long]{self.rank==1 && self.size == n}` but it is often convenient to give a shorter name:

```java
type Vec(n:Long) = x10.regionarray.Array[Long]{self.rank==1, self.size == n};
var example : Vec(78L);
```

The following examples are legal type definitions,

```java
import x10.util.*;
import x10.regionarray.*;
class TypeExamples {
    static type StringSet = Set[String];
    static type MapToList[K,V] = Map[K,List[V]];
    static type Long(x: Long) = Long{self==x};
    static type Dist(r: Long) = Dist{self.rank==r};
    static type Dist(r: Region) = Dist{self.region==r};
    static type Redund(n:Long, r:Region){r.rank==n} = Dist{rank==n && region==r};
}
```

The following code illustrates that type definitions are applicative rather than generative. `B` and `C` are both aliases for `String`, rather than new types, and so are interchangeable with each other and with `String`. Similarly, `A` and `Long` are equivalent.

```java
def someTypeDefs () {
    type A = Long;
    type B = String;
    type C = String;
    a: A = 3;
    b: B = new C("Hi");
    c: C = b + ", Mom!";
}
```
4.5 Constrained types

Basic types, like Long and List[String], provide useful descriptions of data. However, one frequently wants to say more. One might want to know that a String variable is not null, or that a matrix is square, or that one matrix has the same number of columns as another has rows (so they can be multiplied). In the multicore setting, one might wish to know that two values are located at the same processor, or that one is located at the same place as the current computation.

In most languages, there is simply no way to say and check these things statically. Programmers must make do with comments, assert statements, and dynamic tests. X10 programs can do better, with constraints on types, and guards on class, method and type definitions.

A constraint expression is a Boolean expression e of a quite limited form (§4.5.2). A constraint expression c may be attached to a basic type T, giving a constrained type T{c}. The values of type T{c} are the values of T for which c is true. Constraint expressions also serve as guards on methods (§8.4) and functions (§10.3), and invariants on unit types (§8.9).

When constraining a value of type T, self refers to the object of type T which is being constrained. For example, Long{self != 0} is the type of Longs which are equal to 4 – the best possible description of 4, and a very difficult type to express without using self.

Example:

- Long{self != 0} is the type of non-zero Longs.
- Long{self == 0} is the type of Longs which are zero.
- Long{self != 0, self != 1} is the type of Longs which are neither zero nor one.
- Long{self == 0, self == 1} is the type of Longs which are both zero and one. There are no such values, so it is an empty type.
- String{self != null} is the type of non-null strings.
- Suppose that Matrix is a matrix class with properties rows and cols. Matrix{self.rows == self.cols} is the type of square matrices.
- One way to say that a has the same number of columns that b has rows (so that a*b is a valid matrix product), one could say:
  
  val a : Matrix = someMatrix() ;
  var b : Matrix{b.rows == a.cols} ;
T{e} is a dependent type, that is, a type dependent on values. The type T is called the base type and e is called the constraint. If the constraint is omitted, it is true—that is, the base type is unconstrained.

Constraints may refer to immutable values in the local environment:

```
val n = 1;
var p : Point{rank == n};
```

In a val variable declaration, the variable itself is in scope in its type, and can be used in constraints.

**Example:** For example, `val nz : Long{nz != 0} = 1;` declares a non-zero variable nz. In this case, nz could have been declared as `val nz : Long{self != 0} = 1.`

### 4.5.1 Examples of Constraints

Example of entailment and subtyping involving constraints.

- `Long{self == 3} <: Long{self != 14}.` The only value of `Long{self == 3}` is 3. All integers but 14 are members of `Long{self != 14}`, and in particular 3 is.

- Suppose we have classes `Child <: Person`, and `Person` has a `ssn:Long` property. If `rhys : Child{ssn == 123456789}`, then `rhys` is also a `Person`. `rhys`'s `ssn` field is the same, 123456789, whether `rhys` is regarded as a `Child` or a `Person`. Thus, `rhys : Person{ssn==123456789}` as well. So,

  ```
  Child{ssn == 123456789} <: Person{ssn == 123456789}.
  ```

- Furthermore, since `123456789 != 555555555`, it is clear that `rhys : Person{ssn != 555555555}`. So,

  ```
  Child{ssn == 123456789} <: Person{ssn != 555555555}.
  ```

- `T{e} <: T` for any type T. That is, if you have a value v of some base type T which satisfied e, then v is of that base type T (with the constraint ignored).

- If `A <: B`, then `A{c} <: B{c}` for every constraint `{c}` for which `A{c}` and `B{c}` are defined. That is, if every A is also a B, and a : A{c}, then a is an A and c is true of it. So a is also a B (and c is still true of it), so a : B{c}.

Constraints can be used to express simple relationships between objects, enforcing some class invariants statically. For example, in geometry, a line is determined by two distinct points; a Line struct can specify the distinctness in a type constraint.

---

5We call them Position to avoid confusion with the built-in class Point. Also, Position is a struct rather than a class so that the non-equality test `start != end` compares the coordinates. If Position were a class, `start != end` would check for different Position objects, which might have the same coordinates.
4.5. CONSTRAINED TYPES

```java
struct Position(x: Long, y: Long) {}
struct Line(start: Position, end: Position){start != end}
{}
```

Extending this concept, a Triangle can be defined as a figure with three line segments which match up end-to-end. Note that the degenerate case in which two or three of the triangle’s vertices coincide is excluded by the constraint on Line. However, not all degenerate cases can be excluded by the type system; in particular, it is impossible to check that the three vertices are not collinear.

```java
struct Triangle
(a: Line,
 b: Line{a.end == b.start},
 c: Line{b.end == c.start && c.end == a.start})
{}
```

The Triangle class automatically gets a ternary constructor which takes suitably constrained a, b, and c and produces a new triangle.

A constrained type may be constrained further: the type $S\{c\}{d}$ is the same as the type $S\{c, d\}$. Multiple constraints are equivalent to conjoined constraints: $S\{c, d\}$ in turn is the same as $S\{c \&\& d\}$.

4.5.2 Syntax of constraints

Only a few kinds of expressions can appear in constraints. For fundamental reasons of mathematical logic, the more kinds of expressions that can appear in constraints, the harder it is to compute the essential properties of constrained types – in particular, the harder it is to compute $A\{c\} <: B\{d\}$ or even $E : T\{c\}$. It doesn’t take much to make this basic fact undecidable. In order to make sure that it stays decidable, X10 places stringent restrictions on constraints.

Only the following forms of expression are allowed in constraints.

**Value expressions in constraints** may be:

1. Literal constants, like 3 and `true`;
2. Accessible, immutable (val) variables and parameters;
3. `this`, if the constraint is at a point in the program where `this` is defined, but not in `extends` or `implements` clauses or class invariants;
4. `here`, if the constraint is at a point in the program where `here` is defined;
5. `self`;
6. A field selection expression `t.f`, where `t` is a value expression allowed in constraints, and `f` is a field of `t`’s type. If `t` is `self`, then `f` must be a property, not an arbitrary field.
7. Invocations of property methods, \( p(a, b, \ldots, c) \) or \( a.p(b, c, \ldots d) \), where the receiver and arguments must be value expressions acceptable in constraints, as long as the expansion (viz., the expression obtained by taking the body of the definition of \( p \), and replacing the formal parameters by the actual parameters) of the invocation is allowed as a value expression in constraints.

For an expression `self.p` to be legal in a constraint, \( p \) must be a property. However terms \( t.f \) may be used in constraints (where \( t \) is a term other than `self` and \( f \) is an immutable field.)

Constraints may be any of the following, where all value expressions are of the forms which may appear in constraints:

1. Equalities \( e == f \);
2. Inequalities of the form \( e != f \);
3. Conjunctions of Boolean expressions that may appear in constraints (but only in top-level constraints, not in Boolean expressions in constraints);
4. Subtyping and supertyping expressions: \( T <: U \) and \( T :> U \);
5. Type equalities and inequalities: \( T == U \) and \( T != U \);
6. Invocations of a property method, \( p(a, b, \ldots, c) \) or \( a.p(b, c, \ldots d) \), where the receiver and arguments must be value expressions acceptable in constraints, as long as the expansion of the invocation is allowed as a constraint.
7. Testing a type for a default: \( T \ haszero \).

Note that constraints on methods may include private, protected, or package-protected fields. It is possible to have a method whose guard cannot be directly checked, or even whose result type cannot be expressed as a clause in the program, at some call sites. Nonetheless, X10 uses a broader *internal* type representation, not limited by access rules, and can work with fields in types even though those fields cannot be used in executable code.

**Example:** *This phenomenon can be used to implement a form of compile-type capability checking. We give a minimal example, providing only security by obscurity: users unaware that the *key* method returns the required key will be unable to use the *secret* method. This approach can be strengthened to provide better security.*

The class `Keyed` has a private field `k`. The method `secret(q)` can only be called when \( q == k \). In a larger example, `secret` could be some privileged behavior or secret, available only to callers with proper authority.

At the call site in `Snooper`, `keyed.secret()` is called. It *can’t* be called as `keyed.secret(keyed.k)`, because `k` is a private field. It *can’t* be called as `keyed.secret(8)`, even though

---

\(^6\)Currently inequalities of the form \( e < f \) are not supported.
keyed.k==8, because there is no proof available that keyed.k==8 — indeed, at this point in the code, the requirement that keyed.k==8 cannot even be expressed in X10. However, the value of keyed.k can be retrieved, using keyed.key(). The type of kk cannot be expressed in Snooper, because it refers to a private field of keyed. However, the compiler’s internal representation is not bound by the rules of privacy, and can track the fact that kk is the same as keyed.k. So, the call keyed.secret(kk) succeeds.

class Keyed {
    private val k : Long;
    public def this(k : Long) {
        this.k = k;
    }
    public def secret(q:Long){q==this.k} = 11;
    public def key():Long{self==this.k} = this.k;
}

class Snooper {
    public static def main(argv:Rail[Char]) {
        val keyed : Keyed = new Keyed(8);
        //ERROR: keyed.secret(keyed.k);
        //ERROR: keyed.secret(8);
        val kk = keyed.key();
        keyed.secret(kk);
    }
}

Note: Constraints may not contain casts. In particular, comparisons of values of incompatible types are not allowed. If i:Long, then i==0 is allowed as a constraint, but i==0L is an error, and i as Long==0L is outside of the constraint language.

Semantics of constraints

The logic of constraints is designed to allow a common and important X10 idiom:

class Thing(p:Long){}
    static def example(){
        var x : Thing{x.p==3} = null;
    }

That is, null must be an instance of Thing{x.p==3}. Of course, it cannot be the case that null.p==3 — nor can it equal anything else. When evaluated at runtime, null.p must throw a NullPointerException rather than returning any value at all.

So, X10’s logic of constraints — unlike the logic of runtime — allows x=null to satisfy x.p==3. Building this logic requires a few definitions.

The property graph, at an instant in an X10 execution, is the graph whose nodes are all objects in existence at that instance, plus null, with an edge from x to y if x is
an object with a property whose value is \( y \). The rules for constructors guarantee that property graphs are acyclic, which is crucial for decidability.

As is standard in mathematical logic, we introduce the concept of a valuation \( v \), which is a mapping from variable names to their values – in our case, nodes of an X10 property graph. A valuation \( v \) can be extended to values to all constraint formulas. The crucial definitions are:

\[
v(a.b...l.m == n.o...y.z) = \\
\text{a=null \lor a.b=null \lor ... a.b...l=null} \\
\text{\lor n=null \lor n.o=null \lor ... n.o...y=null} \\
\text{\lor v(a).b...l.m = v(n).o...y.}
\]

\[
v(a.b...l.m != n.o...y.z) = \\
\text{a=null \lor a.b=null \lor ... a.b...l=null} \\
\text{\lor n=null \lor n.o=null \lor ... n.o...y=null} \\
\text{\lor v(a).b...l.m \neq v(n).o...y.}
\]

For example, \( v(a.b==1) \) is true if either \( v(a) = \text{null} \) or if \( v(a) \) is a container whose \( b \)-field is equal to \( 1 \). While such a valuation is perfectly well-defined, it has properties that need to be understood in light of the fact that \( == \) is not mathematical equality. Given any valuation in which \( v(a) = \text{null} \), both \( v(a.b==1 \&\& a.b==2) \) and \( v(a.b==1 \&\& a.b!=1) \) are true. This does not contradict logic and mathematics, it does not imply that \( v(\text{false}) \) is true (it’s not), and it does not assert that in X10 there is a number which is both 1 and 2. It simply reflects the fact that, while \( == \) is similar to mathematical equality in many respects, it is ultimately a different operation, and in constraints it is given a null-safe interpretation.

From this definition of valuation, we define entailment in the standard way. Given constraints \( c \) and \( d \), we define \( c \) entails \( d \), sometimes written \( c \models d \), if for all valuations \( v \) such that \( v(c) \) is true, \( v(d) \) is also true.

**Limitation:** Although nearly-contradictory conjunctions like \( x.a==1 \&\& x.a==2 \) entail \( x==\text{null} \), X10’s constraint solver does not currently use this rule. If you want \( x==\text{null} \), write \( x==\text{null} \).

Subtyping of constrained types is defined in terms of entailment. \( S[S_1, \ldots, S_m] \{c\} \) is a subtype of \( T[T_1, \ldots, T_n] \{d\} \) if \( S[S_1, \ldots, S_m] \) is a subtype of \( T[T_1, \ldots, T_n] \) and \( c \) entails \( d \).

For examples of constraints and entailment, see (§4.5.1)

### 4.5.3 Constraint solver: incompleteness and approximation

The constraint solver is sound in that if it claims that \( c \) entails \( d \) then in fact it is the case that every valuation that satisfies \( c \) satisfies \( d \).

---

7 No experienced programmer should actually think that \( == \) is mathematical equality in any case. It is quite common for two objects to appear identical but not be \( == \). X10’s discrepancy between the two concepts is orthogonal to the familiar one.
4.5. CONSTRANGED TYPES

Limitation: X10’s constraint solver is incomplete. There are situations in which c entails d but the solver cannot establish it. For instance it cannot establish that a != b && a != c && b != c entails false if a, b, and c are of type Boolean. Similarly, although a.b==1 && a.b==2 entails a==null, the constraint solver does not deduce this fact.

4.5.4 Acyclicity of Properties

To ensure that typechecking is decidable, X10 requires that the graph whose nodes are types, with edges from types to the properties of those types, be acyclic. This is often stated as “properties are acyclic.” That is, given a container type T, T cannot have a property of type T, nor a property which has a property of type T, nor a property which has a property with a property of type T, etc.

Example: The following is forbidden by the acyclicity requirement, as ERRORList[T] would have a property, tail, which is also an ERRORList[T].

    class ERRORList[T](head:T, tail: ERRORList[T]) {}

Without this restriction, typechecking becomes undecidable.

4.5.5 Limitation: Generics and Constraints at Runtime

The X10 runtime does not maintain a representation of constraints as part of the runtime representation of a type. While there various approaches which could be used, they would require far higher prices in space or time than they are worth. A representation suitable for one use of types (such as keeping a closure for testing membership in the type) is unsuitable for others (such as determining if one type is a subtype of another). Furthermore, it would be necessary to compute entailment at runtime, which is currently impractical.

Rather than pay the runtime costs for keeping and manipulating constraints (which can be considerable), X10 omits them. However, this renders certain type checks uncertain: X10 needs some information at runtime, but does not have it. In particular, casts to instances of generic types, and to type variables, are potentially troublesome.

Example: The following code illustrates the dangers of casting to generic types. It constructs a rail a of Long{self==3}’s – integers which are statically known to be 3. The only number that can be stored into a is 3. Then it tricks the compiler into thinking that it is a rail of Long, without restriction on the elements, giving it the name b at that type. The cast aa as Rail[Long] is a cast to an instance of a generic type, which is the problem.

But, it can store any Long into the elements of b, thereby violating the invariant that all the elements of the rail are 3. This could lead to program failures, as illustrated by the failing assertion.

With the –VERBOSE compiler option, X10 prints a warning about the declaration of b.
val a = new Rail[Long{self==3}](10, 3);
// a(0) = 1; would be illegal
a(0) = 3; // LEGAL
val aa = a as Any;
val b = aa as Rail[Long]; // WARNED with -VERBOSE
b(0) = 1;
val x : Long{self==3} = a(0);
assert x == 3 : "This fails at runtime."

Since constraints are not preserved at runtime, instanceof and as cannot pay attention to them. When types are used generically, they may not behave as one would expect were one to imagine that their constraints were kept. Specifically, constraints at runtime are, in effect, simply replaced by true.

**Example:** The following code defines generic methods inst and cast, which look like generic versions of instanceof and as. The example() code shows that inst and cast behave quite differently from instanceof and as, due to the loss of constraint information.

The first section of asserts shows the behavior of instanceof and at. We have a value pea, such that pea.p==1. It behaves as if its p field were 1: it answers true to self.p==1, and false to self.p==2. This is entirely as desired.

The following section of assert and val statements does the analogous thing, but using the generic methods inst and cast rather than the built-in operations instanceof and as. pea answers true to inst checks concerning both Pea{p==1} and Pea{p==2}, and can be cast() into both these types. This behavior is not what one would expect from runtime types that keep constraint information. It is, however, precisely what one would expect from runtime types that have their constraints replaced by true.

The cast2 line shows how to use this fact to violate the constraint system at runtime. This dynamic cast produces an object of type Pea{p==2} for which p!=2.

Note that the -VERBOSE compiler flag will produce a warning that cast is unsound.

class Generic {
    public static def inst[T](x:Any):Boolean = x instanceof T;
    // With -VERBOSE, the following line gets a warning
    public static def cast[T](x:Any):T = x as T;
}
class Pea(p:Long) {}
class Example{
    static def example() {
        val pea : Pea = new Pea(1);
        // These are what you'd expect:
        assert (pea instanceof Pea{p==1});
        assert (pea as Pea{p==1}).p == 1;
        assert ! (pea instanceof Pea{p==2});
        // 'val x = pea as Pea{p==2};'
        // throws a FailedDynamicCheckException.
4.6. FUNCTION TYPES

// But the genericized versions don't do the same thing:
assert Generic.inst[Pea{p==1}](pea);
assert Generic.inst[Pea{p==2}](pea);
// No exception here!
val cast1: Pea{p==1} = Generic.cast[Pea{p==1}](pea);
val cast2: Pea{p==2} = Generic.cast[Pea{p==2}](pea);
assert cast2.p == 1;
assert !(cast2 instanceof Pea{p==2});
}

While in some cases it would be possible to keep constraints around at runtime and operate efficiently on them, in other cases it would not.

4.6 Function types

FunctionType ::= TypeParams? (FormalList?) Guard? => Type

For every sequence of types \(T_1, \ldots, T_n, T\), and \(n\) distinct variables \(x_1, \ldots, x_n\) and constraint \(c\). the expression \((x_1:T_1, \ldots, x_n:T_n)\{c\}=>T\) is a function type. It stands for the set of all functions \(f\) which can be applied to a list of values \((v_1, \ldots, v_n)\) provided that the constraint \(c[v_1, \ldots, v_n, p/x_1, \ldots, x_n]\) is true, and which returns a value of type \(T[v_1, \ldots, v_n/x_1, \ldots, x_n]\). When \(c\) is true, the clause \(\{c\}\) can be omitted. When \(x_1, \ldots, x_n\) do not occur in \(c\) or \(T\), they can be omitted. Thus the type \((T_1, \ldots, T_n)=>T\) is actually shorthand for \((x_1:T_1, \ldots, x_n:T_n)\{true\}=>T\), for some variables \(x_1, \ldots, x_n\).

Limitation: Constraints on closures are not supported. They parse, but are not checked.

X10 functions, like mathematical functions, take some arguments and produce a result. X10 functions, like other X10 code, can change mutable state and throw exceptions. Closures (§10) are of function type – and so are rails and arrays.

Example: Typical functions are the reciprocal function:

val recip = (x : Double) => 1/x;

and a function which increments element \(i\) of a rail \(r\), or throws an exception if there is no such element, where, for the sake of example, we constrain the type of \(i\) to avoid one of the many longs which are not possible subscripts:

val inc = (r:Rail[Long], i: Long{i != r.size}) => {
  if (i < 0 || i >= r.size) throw new DoomExn();
  r(i)++;
};
In general, a function type needs to list the types \( T_i \) of all the formal parameters, and their distinct names \( x_i \) in case other types refer to them; a constraint \( c \) on the function as a whole; a return type \( T \).

\[
(x_1: T_1, \ldots, x_n: T_n){c} \Rightarrow T
\]

The names of the formal parameters, \( x_i \), are bound in the type. As usual with bound variables, they can be given new names without changing the meaning of the type. In particular, the names of formals in a function type do not need to be the same as the names in the function in a value of that type.

**Example:** The type of \( \text{id} \) uses the bound variable \( x \). The type of \( \text{ie} \) uses the bound variable \( z \), but is otherwise identical to that of \( \text{id} \). The two types are the same, as shown by the assignment of \( \text{id} \) to \( \text{ie} \). Also, \( \text{id}' \)s type uses \( x \), and \( \text{id}' \)s value uses \( y \).

```scala
def id(x: Long): Long = x
def ie(z: Long): Long = id
```

**Limitation:** Function types differing only in the names of bound variables may wind up being considered different in X10 v2.2, especially if the variables appear in constraints.

The formal parameter names are in scope from the point of definition to the end of the function type—they may be used in the types of other formal parameters and in the return type. Value parameters names may be omitted if they are not used; the type of the reciprocal function can be written as \((\text{Double})\Rightarrow\text{Double}\).

A function type is covariant in its result type and contravariant in each of its argument types. That is, let \( S_1, \ldots, S_n, S, T_1, \ldots T_n, T \) be any types satisfying \( S_i <: T_i \) and \( S <: T \). Then \((x_1: T_1, \ldots, x_n: T_n){c} \Rightarrow S\) is a subtype of \((x_1: S_1, \ldots, x_n: S_n){c} \Rightarrow T\).

A class or struct definition may use a function type

\[
F = (x_1:T_1, \ldots, x_n:T_n){c} \Rightarrow T
\]

in its implements clause; this is equivalent to implementing an interface requiring the single operator

```
public operator this(x1:T1,...,xn:Tn){c}:T
```

Similarly, an interface definition may specify a function type \( F \) in its \textbf{extends} clause. Values of a class or struct implementing \( F \) can be used as functions of type \( F \) in all ways. In particular, applying one to suitable arguments calls the \texttt{apply} method.

**Limitation:** A class or struct may not implement two different instantiations of a generic interface. In particular, a class or struct can implement only one function type.

A function type \( F \) is not a class type in that it does not extend any type or implement any interfaces, or support equality tests. \( F \) may be implemented, but not extended, by a class or function type. Nor is it a struct type, for it has no predefined notion of equality.
### 4.7 Default Values

Some types have default values, and some do not. Default values are used in situations where variables can legitimately be used without having been initialized: types without default values cannot be used in such situations. For example, a field of an object

```scala
var x:T
```

can be left uninitialized if \( T \) has a default value; it cannot be if \( T \) does not. Similarly, a transient (§8.2.3) field transient val x:T is only allowed if \( T \) has a default value.

Default values, or lack of them, is defined thus:

- The fundamental numeric types (Int, UInt, Long, ULong, Short, UShort, Byte, UByte, Float, Double) all have default value 0.
- Boolean has default value false.
- Char has default value '\0'.
- If every field of a struct type \( T \) has a default value, then \( T \) has a default value. If any field of \( T \) has no default value, then \( T \) does not. (§9.7)
- A function type has a default value of null.
- A class type has a default value of null.
- The constrained type \( T\{c\} \) has the same default value as \( T \) if that default value satisfies \( c \). If the default value of \( T \) doesn’t satisfy \( c \), then \( T\{c\} \) has no default value.

**Example:** var \( x: \text{Long}\{x != 4\} \) has default value 0, which is allowed because 0 != 4 satisfies the constraint on x. var \( y: \text{Long}\{y==4\} \) has no default value, because 0 does not satisfy \( y==4 \). The fact that \( \text{Long}\{y==4\} \) has precisely one value, viz. 4, doesn’t matter: the only candidate for its default value, as for any subtype of Long, is 0. \( y \) must be initialized before it is used.

The predicate \( T \text{ haszero} \) tells if the type \( T \) has a default value. haszero may be used in constraints.

**Example:** The following code defines a sort of cell holding a single value of type \( T \). The cell is initially empty – that is, has \( T \)’s zero value – but may be filled later.

```scala
class Cell0[T]{T haszero} {
    public var contents : T;
    public def put(t:T) { contents = t; }
}
```

The built-in type Zero has the method \( \text{get}[T]() \) which returns the default value of type \( T \).

**Example:** As a variation on a theme of Cell0, we define a class Cell1[T] which can be initialized with a value of an arbitrary type \( T \), or, if \( T \) has a default value, can be created with the default value. Note that \( T \text{ haszero} \) is a constraint on one of the constructors, not the whole type:
class Cell1[T] {
    public var contents: T;
    def this(t:T) { contents = t; }
    def this(){T haszero} { contents = Zero.get[T](); }
    public def put(t:T) {contents = t;}
}

4.8 Annotated types

Any X10 type may be annotated with zero or more user-defined type annotations \(\text{[17]}\). Annotations are defined as (constrained) interface types and are processed by compiler plugins, which may interpret the annotation symbolically.

A type \(T\) is annotated by interface types \(A_1, \ldots, A_n\) using the syntax \(@A_1 \ldots @A_n T\).

4.9 Subtyping and type equivalence

Intuitively, type \(T_1\) is a subtype of type \(T_2\), written \(T_1 <: T_2\), if every instance of \(T_1\) is also an instance of \(T_2\). For example, Child is a subtype of Person (assuming a suitably defined class hierarchy): every child is a person. Similarly, \(\text{Long\{self != }\theta\text{\}}\) is a subtype of \(\text{Long}\) – every non-zero integer is an integer.

This section formalizes the concept of subtyping. Subtyping of types depends on a type context, viz., a set of constraints on type parameters and variables that occur in the type. For example:

```java
class ConsTy[T,U] {
    def upcast(t:T){T <: U} :U = t;
}
```

Inside `upcast`, \(T\) is constrained to be a subtype of \(U\), and so \(T <: U\) is true, and \(t\) can be treated as a value of type \(U\). Outside of `upcast`, there is no reason to expect any relationship between them, and \(T <: U\) may be false. However, subtyping of types that have no free variables does not depend on the context. \(\text{Long\{self != }\theta\text{\}} <: \text{Long}\) is always true.

**Limitation:** Subtyping of type variables does not work under all circumstances in the X10 2.2 implementation.

- **Reflexivity:** Every type \(T\) is a subtype of itself: \(T <: T\).
- **Transitivity:** If \(T <: U\) and \(U <: V\), then \(T <: V\).
4.10. COMMON ANCESTORS OF TYPES

- **Direct Subclassing:** Let \( \vec{X} \) be a (possibly empty) vector of type variables, and \( \vec{Y}, \vec{Y}_i \) be vectors of type terms over \( \vec{X} \). Let \( \vec{T} \) be an instantiation of \( \vec{X} \), and \( \vec{U}, \vec{U}_i \) the corresponding instantiation of \( \vec{Y}, \vec{Y}_i \). Let \( c \) be a constraint, and \( c' \) be the corresponding instantiation. We elide properties, and interpret empty vectors as absence of the relevant clauses. Suppose that \( C \) is declared by one of the forms:

1. `class C[\vec{X}]{c} extends D[\vec{Y}]{d}
   implements I_1[\vec{Y}_1]{i_1}, ..., I_n[\vec{Y}_n]{i_n}`
2. `interface C[\vec{X}]{c} extends I_1[\vec{Y}_1]{i_1}, ..., I_n[\vec{Y}_n]{i_n}`
3. `struct C[\vec{X}]{c} implements I_1[\vec{Y}_1]{i_1}, ..., I_n[\vec{Y}_n]{i_n}`

Then:
1. \( C[\vec{T}] <: D[\vec{U}]{d} \) for a class
2. \( C[\vec{T}] <: I_i[\vec{U}_i]{i_i} \) for all cases.
3. \( C[\vec{T}] <: C[\vec{T}]{c'} \) for all cases.

- **Function types:**
  \[(x_1: T_1, \ldots, x_n: T_n){c} => T\]
  is a subtype of
  \[(x'_1: T'_1, \ldots, x'_n: T'_n){c'} => T'\]
  if:
  1. Each \( T_i <: T'_i \);
  2. \( c[x'_1, \ldots, x'_n / x_1, \ldots, x_n] \) entails \( c' \);
  3. \( T' <: T \);

- **Constrained types:** \( T{c} \) is a subtype of \( T{d} \) if \( c \) entails \( d \).

- **Any:** Every type \( T \) is a subtype of \( x10.lang.Any \).

- **Type Variables:** Inside the scope of a constraint \( c \) which entails \( A <: B \), we have \( A <: B \). e.g., upcast above.

Two types are *equivalent*, \( T == U \), if \( T <: U \) and \( U <: T \).

### 4.10 Common ancestors of types

There are several situations where X10 must find a type \( T \) that describes values of two or more different types. This arises when X10 is trying to find a good type for:

- Conditional expressions, like `test ? 0 : "non-zero"` or even `test ? 0 : 1;`
• Rail construction, like [0, "non-zero"] and [0, 1];

• Functions with multiple returns, like

```hs
def f(a:Long) {
  if (a == 0) return 0;
  else return "non-zero";
}
```

In some cases, there is a unique best type describing the expression. For example, if B and C are direct subclasses of A, pick will have return type A:

```hs
static def pick(t:Boolean, b:B, c:C) = t ? b : c;
```

However, in many common cases, there is no unique best type describing the expression. For example, consider the expression E

```hs
b ? 0 : 1 // Call this expression E
```

The best type of 0 is Long{self==0}, and the best type of 1 is Long{self==1}. Certainly E could be given the type Long, or even Any, and that would describe all possible results. However, we actually know more. Long{self != 2} is a better description of the type of E—certainly the result of E can never be 2. Long{self != 2, self != 3} is an even better description; E can’t be 3 either. We can continue this process forever, adding integers which E will definitely not return and getting better and better approximations. (If the constraint sublanguage had ||, we could give it the type Long{self == 0 || self == 1}, which would be nearly perfect. But || makes typechecking far more expensive, so it is excluded.) No X10 type is the best description of E; there is always a better one.

Similarly, consider two unrelated interfaces:

```hs
interface I1 {}
interface I2 {}
class A implements I1, I2 {}
class B implements I1, I2 {}
class C {
  static def example(t:Boolean, a:A, b:B) = t ? a : b;
}
```

I1 and I2 are both perfectly good descriptions of t ? a : b, but neither one is better than the other, and there is no single X10 type which is better than both. (Some languages have conjunctive types, and could say that the return type of example was I1 &\& I2. This, too, complicates typechecking.)

So, when confronted with expressions like this, X10 computes some satisfactory type for the expression, but not necessarily the best type. X10 provides certain guarantees about the common type V{v} computed for T{t} and U{u}:
4.11. FUNDAMENTAL TYPES

If \( T \{ t \} == U \{ u \} \), then \( V \{ v \} == T \{ t \} == U \{ u \} \). So, if X10’s algorithm produces an utterly untenable type for \( a \ ? \ b : c \), and you want the result to have type \( T \{ t \} \), you can (in the worst case) rewrite it to

\[ a \ ? \ b \text{ as } T \{ t \} : c \text{ as } T \{ t \} \]

- If \( T == U \), then \( V == T == U \). For example, X10 will compute the type of \( b ? 0 : 1 \) as \( \text{Long} \{ c \} \) for some constraint \( c \)—perhaps simply picking \( \text{Long} \{ \text{true} \} \), \( \text{viz.} \), \( \text{Long} \).

- X10 preserves place information about GlobalRefs, because it is so important. If both \( t \) and \( u \) entail \( \text{self.home}==p \), then \( v \) will also entail \( \text{self.home}==p \).

- X10 similarly preserves nullity information. If \( t \) and \( u \) both entail \( x == \text{null} \) or \( x != \text{null} \) for some variable \( x \), then \( v \) will also entail it as well.

- The computed upper bound of function types with the same argument types is found by computing the upper bound of the result types. If \( T = (T_1, \ldots, T_n) => T' \) and \( U = (T_1, \ldots, T_n) => U' \), and \( V' \) is the computed upper bound of \( T' \) and \( U' \), then the computed upper bound of \( T \) and \( U \) is \( U = (T_1, \ldots, T_n) => V' \). (But, if the argument types are different, the computed upper bound may be \( \text{Any} \).)

4.11 Fundamental types

Certain types are used in fundamental ways by X10.

4.11.1 The interface \( \text{Any} \)

It is quite convenient to have a type which all values are instances of; that is, a supertype of all types.\(^8\) X10’s universal supertype is the interface \( \text{Any} \).

\begin{verbatim}
package x10.lang;
public interface Any {
    def toString():String;
    def typeName():String;
    def equals(Any):Boolean;
    def hashCode():Long;
}
\end{verbatim}

\( \text{Any} \) provides a handful of essential methods that make sense and are useful for everything. \( a\.toString() \) produces a string representation of \( a \), and \( a\.typeName() \) the string representation of its type; both are useful for debugging. \( a\.equals(b) \) is the programmer-overridable equality test, and \( a\.hashCode() \) an integer useful for hashing.

\(^8\)Java, for one, suffers a number of inconveniences because some built-in types like \( \text{long} \) and \( \text{char} \) aren’t subtypes of anything else.
4.12 Type inference

X10 v2.4 supports limited local type inference, permitting certain variable types and return types to be elided. It is a static error if an omitted type cannot be inferred or uniquely determined. Type inference does not consider coercions.

4.12.1 Variable declarations

The type of a val variable declaration can be omitted if the declaration has an initializer. The inferred type of the variable is the computed type of the initializer. For example, val seven = 7; is identical to

val seven: Long{self==7} = 7;

Note that type inference gives the most precise X10 type, which might be more specific than the type that a programmer would write.

Limitation: At the moment, var declarations may not have their types elided in this way.

4.12.2 Return types

The return type of a method can be omitted if the method has a body (i.e., is not abstract or native). The inferred return type is the computed type of the body. In the following example, the return type inferred for isTriangle is Boolean{self==false}

class Shape {
  def isTriangle() = false;
}

Note that, as with other type inference, methods are given the most specific type. In many cases, this interferes with subtyping. For example, if one tried to write:

class Triangle extends Shape {
  def isTriangle() = true;
}

the compiler would reject this program for attempting to override isTriangle() by a method with the wrong type, viz. Boolean{self==true}. In this case, supply the type that is actually intended for isTriangle:

def isTriangle() : Boolean =false;

The return type of a closure can be omitted. The inferred return type is the computed type of the body.

The return type of a constructor can be omitted if the constructor has a body. The inferred return type is the enclosing class type with properties bound to the arguments
4.12. TYPE INFERENCE

in the constructor’s property statement, if any, or to the unconstrained class type. For example, the Spot class has two constructors, the first of which has inferred return type Spot{x==0} and the second of which has inferred return type Spot{x==xx}.

```java
class Spot(x:Long) {
    def this() {property(0);}
    def this(xx: Long) { property(xx); }
}
```

A method or closure that has expression-free return statements (return; rather than return e;) is said to be a void method or closure. void is not a type; there are no void values, nor can void be used as the argument of a generic type. However, void takes the syntactic place of a type in a few contexts. A void method can be specified by def m():void, and similarly for a closure:

```java
def m():void {return;}
val f : () => void = () => {return;};
```

By a convenient abuse of language, void is sometimes lumped in with types; e.g., we may say “return type of a method” rather than the formally correct but rather more awkward “return type of a method that is not a void method”. Despite this informal usage, void is not a type and cannot be used as the value of a type parameter. For example, given

```java
static def eval[T] (f:()=>T):T = f();
```

The call eval[void](f) does not typecheck. There is no way in X10 to write a generic function which works with both functions which return a value and functions which do not. In such cases it may be convenient to define a type Unit thus:

```java
struct Unit{}
```

Functions whose return type is Unit may simply return the expression Unit() which evaluates to the unique value of type Unit. (By definition of equality of structs Unit()==Unit().)

X10 preserves known information when computing return types. A constraint on a method induces a corresponding constraint on its return type.

**Example:** In the following code, the type inferred for x is Numb{self.p==n, n!=0, self!=null}. In particular, the conjunct n != 0 is preserved from the cast of n to Long{self != 0}.

```java
class Numb(p:Long){
    static def dup(n:Long){n != 0} = new Numb(n);
    public static def example(n:Long) {
        val x = dup(n as Long{self != 0});
        val y : Numb{self.p==n, n!=0, self!=null} = x;
    }
}
```
4.12.3 Inferring Type Arguments

A call to a polymorphic method may omit the explicit type arguments. X10 will compute a type from the types of the actual arguments. Failure of the compiler to infer unique types for omitted type arguments is a compile-time error. For instance, given the method definition

\[
def m[X](\ldots)\{
\}
\]

an invocation \( m() \) is considered a compile-time error. The compiler has no idea what \( X \) the programmer intends.

**Example:** Consider the following method, which chooses one of its arguments. (A more sophisticated one might sometimes choose the second argument, but that does not matter for the sake of this example.)

\[
\text{static def choose}(a: X, b: X): X = a;
\]

The type argument \( X \) can always be supplied: \( \text{choose}[\text{Long}](1, 2) \) picks an integer, and \( \text{choose}[\text{Any}](1, "yes") \) picks a value that might be an integer or a string. However, the type argument can be elided. Suppose that \( \text{Sub} <: \text{Super} \); then the following compiles:

\[
\text{static def choose}(a: X, b: X): X = a;
\text{static val j : Any = choose("string", 1);
static val k : Super = choose(new Sub(), new Super());}
\]

The type parameter doesn’t need to be the type of a variable. It can be found inside of the type of a variable; X10 can extract it.

**Example:** The first method below returns the first element of a rail. The type parameter \( T \) represents the type of the rail’s elements. There is no parameter of type \( T \). There is one of type \( \text{Rail}[\text{String}]{\text{length==3}} \). When doing type inference, the compiler is able to infer that \( T \) should be instantiated to \( \text{String} \):

\[
\text{static def first}(x: \text{Rail}[T]) = x(0);
\text{static def example() {\}
  val ss <: \text{Rail}[\text{String}] = ["X10", "Java", "C++"]; // ok
  val s1 <: \text{String} = first(ss); // ok
  assert s1.equals("X10");
}\]

**Sketch of X10 Type Inference for Method Calls**

When the X10 compiler sees a method call

\[
a.m(b_1, \ldots, b_n)
\]

and attempts to infer type parameters to see if it could be a use of a method

\[
def m[X_1, \ldots, X_i](y_1 : S_1, \ldots, y_n:S_n),
\]

it reasons as follows.

Let
4.12. TYPE INFERENCE

Let $T_i$ be the type of $b_i$

Then, the compiler is seeking a set $B$ of type bindings

$$B = \{ \ x_1 = u_1, \ldots, x_t = u_t \}$$

such that $T_i <: S^*_i$ for $1 \leq i \leq n$, where $S^*$ is $S$ with each type variable $x_j$ replaced by the corresponding $u_j$. If it can find such a $B$, it has a usable choice of type arguments and can do the type inference. If it cannot find $B$, then it cannot do type inference. (Note that X10’s type inference algorithm is incomplete – there may be such a $B$ that X10 cannot find. If this occurs in your program, you will have to write down the type arguments explicitly.)

Let $B_0$ be the set $\{ T_i <: S_i | 1 \leq i \leq n \}$. Let $B_{n+1}$ be $B_n$ with one element $F <: G$ or $F = G$ removed, and $\text{Strip}(F <: G)$ or $\text{Strip}(F = G)$, where $\text{Strip}$ is defined below, added. Repeat this until $B_n$ consists entirely of comparisons with type variables (viz., $Y_j = U$, $Y_j <: U$, and $Y_j :> U$), or until some $n$ exceeds a predefined compiler limit.

The candidate inferred types may be read off of $B_n$. The guessed binding for $x_j$ is:

- If there is an equality $x_j = \hat{w}$ in $B_n$, then guess the binding $x_j = \hat{w}$. Note that there may be several such equalities with different choices of $\hat{w}$; pick any one. If the chosen binding does not equal the others, the candidate binding will be rejected later and type inference will fail.
- Otherwise, if there is one or more upper bounds $x_j <: v_k$ in $B_n$, guess the binding $x_j = v_+$, where $v_+$ is the computed lower bound of all the $v_k$’s.
- Otherwise, if there is one or more lower bounds $r_k :< x_j$, guess that $x_j = r_+$, where $r_+$ is the computed upper bound of all the $r_k$’s.

If this does not yield a binding for some variable $x_j$, then type inference fails. Furthermore, if every variable $x_j$ is given a binding $u_j$, but the bindings do not work — that is, if $a.m[u_1, \ldots, u_t](b_1, \ldots, b_n)$ is not a well-typed call of the original method def $m[X_1, \ldots, X_t](y_1:S_1, \ldots, y_n:S_n)$ — then type inference also fails.

**Computation of the Replacement Elements**  Given a type relation $r$ of the form $F <: G$ or $F = G$, we compute the set $\text{Strip}(r)$ of replacement constraints. There are a number of cases; we present only the interesting ones.

- If $F$ has the form $F'\{c\}$, then $\text{Strip}(r)$ is defined to be $F' = G$ if $r$ is an equality, or $F' <: G$ if $r$ is a subtyping. That is, we erase type constraints. Validity is not an issue at this point in the algorithm, as we check at the end that the result is valid. Note that, if the equation had the form $Z\{c\} = A$, it could be solved by either $Z = A$ or by $Z = A\{c\}$. By dropping constraints in this rule, we choose the former solution, which tends to give more general types in results.
- Similarly, we drop constraints on $G$ as well.
• If $F$ has the form $K[F_1, \ldots, F_k]$ and $G$ has the form $K[G_1, \ldots, G_k]$, then $\text{Strip}(r)$ has one type relation comparing each parameter of $F$ with the corresponding one of $G$:

$$\text{Strip}(r) = \{F_l = G_l | 1 \leq l \leq k\}$$

For example, the constraint $\text{List}[X] = \text{List}[Y]$ induces the constraint $X = Y$. $\text{List}[X] <: \text{List}[Y]$ also induces the same constraint. The only way that $\text{List}[X]$ could be a subtype of $\text{List}[Y]$ in X10 is if $X = Y$. List of different types are incomparable.

• Other cases are fairly routine. E.g., if $F$ is a type-defined abbreviation, it is expanded.

**Example:** Consider the program:

```scala
import x10.util.*;
class Cl[C1, C2, C3]{}
class Example {
  static def me[X1, X2](Cl[Long, X1, X2]) =
    new Cl[X1, X2, Point]();
  static def example() {
    val a = new Cl[Long, Boolean, String]();
    val b : Cl[Boolean, String, Point] = me[Boolean, String](a);
    val c : Cl[Boolean, String, Point] = me(a);
  }
}
```

The method call for $b$ has explicit type parameters. The call for $c$ infers the parameters. The computation starts with one equation, saying that the formal parameter of $\text{me}$ has to be able to accept the actual parameter $a$:

$$\text{Cl}[\text{Long}, \text{Boolean}, \text{String}] <: \text{Cl}[\text{Long}, X_1, X_2]$$

Note that both terms are Cl of three things. This is broken into three equations:

- $\text{Long} = \text{Long}$
- $X_1 = \text{Boolean}$
- $X_2 = \text{String}$

The situation would be more complex if X10 had covariant and contravariant types.
which suggests a value for $X_2$. All of these equations are simple enough, so the algorithm terminates.

Then, $X_{10}$ confirms that the binding $X_1=$Boolean, $X_2=$String actually generates a correct call, which it does.

**Example:** When there is no way to infer types correctly, the type inference algorithm will fail. Consider the program:

```java
public class Failsome {
    static def fail[X](a:Rail[X], b:Rail[X]):void {}
    public static def main(argv:Rail[String]) {
        val aint : Rail[Long] = [1,2,3];
        val abool : Rail[Boolean] = [true, false];
        fail(aint, abool); // THIS IS WRONG
    }
}
```

The type inference computation starts, as always, by insisting that the types of the formals to `fail` are capable of accepting the actuals:

$$B_0 = \{\text{Rail}[\text{Long}] <: \text{Rail}[X], \text{Rail}[\text{Boolean}] <: \text{Rail}[X]\}$$

 Arbitrarily picking the first relation to Strip first, we get:

$$B_1 = \{\text{Long} = X, \text{Rail}[\text{Boolean}] <: \text{Rail}[X]\}$$

and then

$$B_2 = \{\text{Long} = X, \text{Boolean} = X\}$$

(At this point it is clear to a human that $B$ is inconsistent, but the algorithm’s check comes a bit later.) $B_2$ consists entirely of comparisons with type variables, so the loop is over. Arbitrarily picking the first equality, it guesses the binding

$$B = \{X = \text{Long}\}.$$ 

In the validation step, it checks that

$$\text{fail}[\text{Long}](aint, abool)$$

is a well-typed call to `fail`. Of course it is not; `abool` would have to be a value of type `Rail[Long]`, which it is not. So type inference fails at this point. In this case it is correct: there is no way to give a proper type to this program.\footnote{In particular, $X=$Any doesn’t work either. A `Rail[Long]` is not a `Rail[Any]` — and it must not be, for you can put a boolean value into a `Rail[Any]`, but you cannot put a boolean value into an `Rail[Long]`. However, if the types of the arguments had simply been $X$ rather than `Rail[X]`, then type inference would correctly infer $X=$Any.}
4.13 Type Dependencies

Type definitions may not be circular, in the sense that no type may be its own supertype, nor may it be a container for a supertype. This forbids interfaces like `interface Loop extends Loop`, and indirect self-references such as `interface A extends B.C` where `interface B extends A`. The formal definition of this is based on Java’s.

An **entity type** is a class, interface, or struct type.

Entity type $E$ **directly depends on** entity type $F$ if $F$ is mentioned in the `extends` or `implements` clause of $E$, either by itself or as a qualifier within a super-entity-type name.

**Example:** In the following, $A$ **directly depends on** $B$, $C$, $D$, $E$, and $F$. It does not directly depend on $G$.

```java
class A extends B.C implements D.E, F[G] {}
```

It is an ordinary programming idiom to use $A$ as an argument to a generic interface that $A$ implements. For example, `ComparableTo[T]` describes things which can be compared to a value of type $T$. Saying that $A$ implements `ComparableTo[A]` means that one $A$ can be compared to another, which is reasonable and useful:

```java
interface ComparableTo[T] {
    def eq(T):Boolean;
}
class A implements ComparableTo[A] {
    public def eq(other:A) = this.equals(other);
}
```

Entity type $E$ **depends on** entity type $F$ if either $E$ directly depends on $F$, or $E$ directly depends on an entity type that depends on $F$. That is, the relation “depends on” is the transitive closure of the relation “directly depends on”.

It is a static error if any entity type $E$ depends on itself.

4.14 Typing of Variables and Expressions

Variable declarations, field declarations, and some other expressions introduce constraints on their types. These extra constraints represent information that is known at the point of declaration. They are used in deductions and type inference later on – as indeed all constraints are, but the automatically-added constraints are added because they are particularly useful.

Any variable declaration of the form

```scala
val x : A ...
```
4.14. **Typing of Variables and Expressions**

results in declaring \( x \) to have the type \( A\{self==x\} \), rather than simply \( A \). (\( \text{var} \) declarations get no such addition, because \( \text{vars} \) cannot appear in constraints.)

A field or property declaration of the form:

```java
class A {
    ...
    val f : B ...
    ...
}
```

results in declaring \( f \) to be of type \( B\{self==this.f\} \). And, if \( y \) has type \( A\{c\} \), then the type for \( y.f \) has a constraint \( self==y.f \), and, additionally, preserves the information from \( c \).

**Example:**

The following code uses a method \( \text{typeIs}[T](x) \) to confirm, statically, that the type of \( x \) is \( T \) (or a subtype of \( T \)).

On line (A) we confirm that the type of \( x \) has a \( self==x \) constraint. The error line (!A) confirms that a different variable doesn't have the \( self==x \) constraint. (B) shows the extra information carried by a field's type.

(C) shows the extra information carried by a field's type when the object's type is constrained. Note that the constraint \( \text{ExtraConstraint}\{self.n==8\} \) on the type of \( y \) has to be rewritten for \( y.f \) since the constraint \( \text{Long}\{self.n==8\} \) is not correct or even well-typed. In this case, the \( \text{ExtraConstraint} \) whose \( n \)-field is \( 8 \) has the name \( y \), so we can write the desired type with a conjunct \( y.n==8 \) \(^{11}\).

Note that we use one of the extra constraints here – this reasoning requires the information that the type of \( y \) has the constraint \( self==y \), so X10 can infer \( y.n==8 \) from \( self.n==8 \). This sort of inference is the reason why X10 adds these constraints in the first place: without them, even the simplest data flows would be beyond the ability of the type system to detect.

```java
class Extra(n:Long) {
    val f : Long;
    def this(n:Long, f:Long) { property(n); this.f = f; }
    static def typeIs[T](val x:T) {}
    public static def main(argv:Rail[String]) {
        val x : Extra = new Extra(1,2L);
        typeIs[ Extra{self==x} ] (x); // (A)
        val nx: Extra = new Extra(1,2L);
        // ERROR: typeIs[ Extra{self==x} ] (nx); // (!A)
        typeIs[ Long{self == x.f} ] (x.f); // (B)
        val y : Extra{self.n==8} = new Extra(8, 4L);
    }
}
```

\(^{11}\)If \( y \) were an expression rather than a variable, there would be no good way to express its type in X10's type system. (The compiler has a more elaborate internal representation of types, not all of which are expressible in X10 version 2.2.)
Once in a while, the additional information will interfere with other typechecking or type inference. In this case, use \texttt{as} (§11.23) to erase it, using expressions like \texttt{x as A}.

**Example:** The following code creates a one-element rail (§11.26) containing \texttt{x}.

If the \texttt{ERROR} line were to be used, X10 would infer that the type of this rail were \texttt{Rail[T]}, where \( T \) is the type of \texttt{x} — that is, \texttt{Rail[Extra{self==x}]}. \texttt{[x]} is a rail of \texttt{x}'s, not a rail of \texttt{Extras}. Since \texttt{Rail[Extra{self==x}]} is not a subtype of \texttt{Rail[Extra]}, the rail \texttt{[x]} cannot be used in a place where an \texttt{Rail[Extra]} is called for.

The expression \texttt{[x as Extra]} uses a type cast to erase the automatically-added extra information about \texttt{x}. \texttt{x as Extra} simply has type \texttt{Extra}, and thus \texttt{[x as Extra]} is a \texttt{Rail[Extra]} as desired.

```java
class Extra {
    static def useRail(Rail[Extra]) {}
    public static def main(argv:Rail[String]) {
        val x : Extra = new Extra();
        //ERROR: useRail([x]);
        useRail([x as Extra]);
    }
}
```

### 4.15 Limitations of Strict Typing

X10’s type checking provides substantial guarantees. In most cases, a program that passes the X10 type checker will not have any runtime type errors. However, there are a modest number of compromises with practicality in the type system: places where a program can pass the typechecker and still have a type error.

1. As seen in §4.5.5, generic types do not have constraint information at runtime. This allows one to write code which violates constraints at runtime, as seen in the example in that section.

2. The library type \texttt{x10.util.IndexedMemoryChunk} provides a low-level interface to blocks of memory. A few methods on that class are not type-safe. See the API if you must.

3. Custom serialization (§13.3.2) allows user code to construct new objects in ways that can subvert the type system.

4. Code written to use the underlying Java or C++ (§18) can break X10’s guarantees.
5 Variables

A variable is an X10 identifier associated with a value within some context. Variable bindings have these essential properties:

- **Type**: What sorts of values can be bound to the identifier;
- **Scope**: The region of code in which the identifier is associated with the entity;
- **Lifetime**: The interval of time in which the identifier is associated with the entity.
- **Visibility**: Which parts of the program can read or manipulate the value through the variable.

X10 has many varieties of variables, used for a number of purposes.

- Class variables, also known as the static fields of a class, which hold their values for the lifetime of the class.
- Instance variables, which hold their values for the lifetime of an object;
- Array elements, which are not individually named and hold their values for the lifetime of an array;
- Formal parameters to methods, functions, and constructors, which hold their values for the duration of method (etc.) invocation;
- Local variables, which hold their values for the duration of execution of a block.
- Exception-handler parameters, which hold their values for the execution of the exception being handled.

A few other kinds of things are called variables for historical reasons; e.g., type parameters are often called type variables, despite not being variables in this sense because they do not refer to X10 values. Other named entities, such as classes and methods, are not called variables. However, all name bindings enjoy similar concepts of scope and visibility.

**Example:** In the following example, \( n \) is an instance variable, and \( \text{nxt} \) is a local variable defined within the method `bump`\(^1\).

\( ^1 \text{This code is unnecessarily turgid for the sake of the example. One would generally write : public def bump() = ++n;} \)
class Counter {
  private var n : Long = 0;
  public def bump() : Long {
    val nxt = n+1;
    n = nxt;
    return nxt;
  }
}

Both variables have type Long (or perhaps something more specific). The scope of n is the body of Counter; the scope of nxt is the body of bump. The lifetime of n is the lifetime of the Counter object holding it; the lifetime of nxt is the duration of the call to bump. Neither variable can be seen from outside of its scope.

Variables whose value may not be changed after initialization are said to be immutable, or constants (§5.1), or simply val variables. Variables whose value may change are mutable or simply var variables. var variables are declared by the var keyword. val variables may be declared by the val keyword; when a variable declaration does not include either var or val, it is considered val.

A variable—even a val—can be declared in one statement, and then initialized later on. It must be initialized before it can be used (§19).

Example: The following example illustrates many of the variations on variable declaration:

```scala
val a : Long = 0; // Full 'val' syntax
b : Long = 0; // 'val' implied
val c = 0; // Type inferred
var d : Long = 0; // Full 'var' syntax
var e : Long; // Not initialized
var f : Long{self != 100} = 0; // Constrained type
val g : Long; // Init. deferred
if (a > b) g = 1; else g = 2; // Init. done here.
```

5.1 Immutable variables

\[
\text{LocVarDeclStmt} ::= \text{LocVarDecl} ; \tag{20.111}
\]

\[
\text{LocVarDecl} ::= \text{Mods}^2 \text{VarKeyword VariableDeclrs} \tag{20.110}
\]

\[
\text{VariableDeclrs} = \text{VarDeclsr} | \text{VarDeclsWType} | \text{VarKeyword FormalDeclrs}
\]

An immutable (val) variable can be given a value (by initialization or assignment) at most once, and must be given a value before it is used. Usually this is achieved by declaring and initializing the variable in a single statement, such as val x = 3, with syntax (20.110) using the VariableDeclators or VarDeclsWType alternatives.
5.2. INITIAL VALUES OF VARIABLES

Example: After these declarations, \(a\) and \(b\) cannot be assigned to further, or even redeclared:

```java
val a : Long = 10;
val b = (a+1)*(a-1);
// ERROR: a = 11; // vals cannot be assigned to.
// ERROR: val a = 11; // no redeclaration.
```

In three special cases, the declaration and assignment are separate. One case is how constructors give values to \(\texttt{val}\) fields of objects. In this case, production (20.110) is taken, with the \texttt{FormalDeclarators} option, such as \texttt{var n:Long;}.

Example: The \texttt{Example} class has an immutable field \(n\), which is given different values depending on which constructor was called. \(n\) can’t be given its value by initialization when it is declared, since it is not knowable which constructor is called at that point.

```java
class Example {
    val n : Long; // not initialized here
    def this() { n = 1; }
    def this(dummy:Boolean) { n = 2;}
}
```

The second case of separating declaration and assignment is in function and method call, described in §5.4. The formal parameters are bound to the corresponding actual parameters, but the binding does not happen until the function is called.

Example: In the code below, \(x\) is initialized to 3 in the first call and 4 in the second.

```java
val sq = (x:Long) => x*x;
x10.io.Console.OUT.println("3 squared = " + sq(3));
x10.io.Console.OUT.println("4 squared = " + sq(4));
```

The third case is delayed initialization (§19), useful in cases where the code has to make decisions (possibly asynchronously) before assigning values to variables.

5.2 Initial values of variables

Every assignment, binding, or initialization to a variable of type \(T\{c\}\) must be an instance of type \(T\) satisfying the constraint \(\{c\}\). Variables must be given a value before they are used. This may be done by initialization – giving a variable a value as part of its declaration.

Example: These variables are all initialized:

```java
val immut : Long = 3;
var mutab : Long = immut;
val use = immut + mutab;
```
A variable may also be given a value by an assignment. \texttt{var} variables may be assigned to repeatedly. \texttt{val} variables may only be assigned once; the compiler will ensure that they are assigned before they are used (§19).

\textbf{Example:} The variables in the following example are given their initial values by assignment. Note that they could not be used before those assignments, nor could \texttt{immu} be assigned repeatedly.

\begin{verbatim}
var muta : Long;
  // ERROR: println(muta);
muta = 4;
val use2A = muta * 10;
val immu : Long;
  // ERROR: println(immu);
if (cointoss()) {immu = 1;}
else {immu = use2A;}
val use2B = immu * 10;
  // ERROR: immu = 5;
\end{verbatim}

Every class variable must be initialized before it is read, through the execution of an explicit initializer. Every instance variable must be initialized before it is read, through the execution of an explicit or implicit initializer or a constructor. Implicit initializers initialize \texttt{var}s to the default values of their types (§4.7). Variables of types which do not have default values are not implicitly initialized.

Each method and constructor parameter is initialized to the corresponding argument value provided by the invoker of the method. An exception-handling parameter is initialized to the object thrown by the exception. A local variable must be explicitly given a value by initialization or assignment, in a way that the compiler can verify using the rules for definite assignment (§19).

### 5.3 Destructuring syntax

X10 permits a \textit{destructuring} syntax for local variable declarations with explicit initializers, and for formal parameters, of type \texttt{Point}, [§16.3.1] and \texttt{Array}, [§16] A point is a sequence of zero or more \texttt{Long}-valued coordinates; an array is an indexed collection of data. It is often useful to get at the coordinates or elements directly, in variables.

\begin{verbatim}
VariableDeclr ::= Id HasResultType? = VariableInitializer 
  | [ IdList ] HasResultType? = VariableInitializer 
  | Id [ IdList ] HasResultType? = VariableInitializer
\end{verbatim}

The syntax \texttt{val [a_1, \ldots, a_n] = e;}, where \texttt{e} is a \texttt{Point}, declares \texttt{n} \texttt{Long} variables, bound to the precisely \texttt{n} components of the \texttt{Point} value of \texttt{e}; it is an error if \texttt{e} is not a \texttt{Point} with precisely \texttt{n} components. The syntax \texttt{val p[a_1, \ldots, a_n] = e;} is similar, but also declares the variable \texttt{p} to be of type \texttt{Point(n)}.
5.4. FORMAL PARAMETERS

The syntax `val [a₁, ..., aₙ] = e;` where `e` is an `Array[T]` for some type `T`, declares `n` variables of type `T`, bound to the precisely `n` components of the `Array[T]` value of `e`; it is an error if `e` is not a `Array[T]` with `rank==1` and `size==n`. The syntax `val p[a₁, ..., aₙ] = e;` is similar, but also declares the variable `p` to be of type `Array[T]{rank==1,size==n}`.

**Example:** The following code makes an anonymous point with one coordinate 11, and binds `i` to 11. Then it makes a point with coordinates 22 and 33, binds `p` to that point, and `j` and `k` to 22 and 33 respectively.

```java
val [i] : Point = Point.make(11);
assert i == 11L;
val p[j,k] = Point.make(22,33);
assert j == 22L && k == 33L;
val q[l,m] = [44,55] as Point;
assert l == 44L && m == 55L;
//ERROR: val [n] = p;
```

Destructuring is allowed wherever a `Point` or `Array[T]` variable is declared, e.g., as the formal parameters of a method. **Example:** The methods below take a single argument each: a three-element point for `example1`, a three-element array for `example2`. The argument itself is bound to `x` in both cases, and its elements are bound to `a`, `b`, and `c`.

```java
static def example1(x[a,b,c]:Point){}
static def example2(x[a,b,c]:Array[String]{rank==1,size==3L}){}
```

5.4 Formal parameters

Formal parameters are the variables which hold values transmitted into a method or function. They are always declared with a type. (Type inference is not available, because there is no single expression to deduce a type from.) The variable name can be omitted if it is not to be used in the scope of the declaration, as in the type of the method `static def main(Rail[String]):void` executed at the start of a program that does not use its command-line arguments.

`var` and `val` behave just as they do for local variables. In particular, the following `inc` method is allowed, but, unlike some languages, does not increment its actual parameter. `inc(j)` creates a new local variable `i` for the method call, initializes `i` with the value of `j`, increments `i`, and then returns. `j` is never changed.

```java
static def inc(var i:Long) { i += 1; }
static def example() {
  var j : Long = 0;
  assert j == 0;
  inc(j);
  assert j == 0;
}
```
Local variables and Type Inference

Local variables are declared in a limited scope, and, dynamically, keep their values only for so long as the scope is being executed. They may be `var` or `val`. They may have initializer expressions: `var i:Long = 1;` introduces a variable `i` and initializes it to 1. If the variable is immutable (`val`) the type may be omitted and inferred from the initializer type (§4.12).

The variable declaration `val x:T=e;` confirms that `e`’s value is of type `T`, and then introduces the variable `x` with type `T`. For example, consider a class `Tub` with a property `p`.

```scala
class Tub(p:Long){
  def this(pp:Long):Tub{self.p==pp} {property(pp);}
  def example() {
    val t : Tub = new Tub(3);
  }
}
```

produces a variable `t` of type `Tub`, even though the expression `new Tub(3)` produces a value of type `Tub{self.p==3}` – that is, a `Tub` whose `p` field is 3. This can be inconvenient when the constraint information is required.

Including type information in variable declarations is generally good programming practice: it explains to both the compiler and human readers something of the intent of the variable. However, including types in `val t:T=e` can obliterate helpful information. So, X10 allows a documentation type declaration, written

```scala
val t <: T = e
```

This has the same effect as `val t = e`, giving `t` the full type inferred from `e`; but it also confirms statically that that type is at least `T`.

Example: The following gives `t` the type `Tub{self.p==3}` as desired. However, a similar declaration with an inappropriate type will fail to compile.

```scala
val t <: Tub = new Tub(3);
// ERROR: val u <: Long = new Tub(3);
```
Like most other kinds of variables in X10, the fields of an object can be either val or var. val fields can be static (§8.2). Field declarations may have optional initializer expressions, as for local variables, §5.5. var fields without an initializer are initialized with the default value of their type. val fields without an initializer must be initialized by each constructor.

For val fields, as for val local variables, the type may be omitted and inferred from the initializer type (§4.12). var fields, like var local variables, must be declared with a type.
6 Names and packages

6.1 Names

An X10 program consists largely of giving names to entities, and then manipulating the entities by their names. The entities involved may be compile-time constructs, like packages, types and classes, or run-time constructs, like numbers and strings and objects.

X10 names can be simple names, which look like identifiers: vj, x10, AndSoOn. Or, they can be qualified names, which are sequences of two or more identifiers separated by dots: x10.lang.String, somePack.someType, a.b.c.d.e.f. Some entities have only simple names; some have both simple and qualified names.

Every declaration that introduces a name has a scope: the region of the program in which the named entity can be referred to by a simple name. In some cases, entities may be referred to by qualified names outside of their scope. E.g., a public class C defined in package p can be referred to by the simple name C inside of p, or by the qualified name p.C from anywhere.

Many sorts of entities have members. Packages have classes, structs, and interfaces as members. Those, in turn, have fields, methods, types, and so forth as members. The member x of an entity named E (as a simple or qualified name) has the name E.x; it may also have other names.

6.1.1 Shadowing

One declaration d may shadow another declaration d’ in part of the scope of d’, if d and d’ declare variables with the same simple name n. When d shadows d’, a use of n might refer to d’s n (unless some d” in turn shadows d), but will never refer to d’s n.

X10 has four namespaces:

- **Types**: for classes, interfaces, structs, and defined types.
- **Values**: for val- and var-bound variables; fields; and formal parameters of all sorts.
• **Methods:** for methods of classes, interfaces, and structs.

• **Packages:** for packages.

A declaration \( d \) in one namespace, binding a name \( n \) to an entity \( e \), shadows all other declarations of that name \( n \) in scope at the point where \( d \) is declared. This shadowing is in effect for the entire scope of \( d \). Declarations in different namespaces do not shadow each other. Thus, a local variable declaration may shadow a field declaration, but not a class declaration.

Declarations which only introduce qualified names — in X10, this is only package declarations — cannot shadow anything.

The rules for shadowing of imported names are given in §6.4.

### 6.1.2 Hiding

Shadowing is ubiquitous in X10. Another, and considerably rarer, way that one definition of a given simple name can render another definition of the same name unavailable is *hiding*. If a class `Super` defines a field named `x`, and a subclass `Sub` of `Super` also defines a field named `x`, and \( b : Sub \), then \( b.x \) is `Sub`'s `x` field, not `Super`'s. In this case, `Super`'s `x` is said to be *hidden*.

Hiding is technically different from shadowing, because hiding applies in more circumstances: a use of class `Sub`, such as `sub.x`, may involve hiding of name `x`, though it could not involve shadowing of `x` because `x` need not be declared as a name at that point.

### 6.1.3 Obscuring

The third way in which a definition of a simple name may become unavailable is *obscuring*. This well-named concept says that, if \( n \) can be interpreted as two or more of: a variable, a type, and a package, then it will be interpreted as a variable if that is possible, or a type if it cannot be interpreted as a variable. In this case, the unavailable interpretations are *obscured*.

**Example:** *In the example method of the following code, both a struct and a local variable are named `eg`. Following the obscuring rules, the call `eg.ow()` in the first assert uses the variable rather than the struct. As the second assert demonstrates, the struct can be accessed through its fully-qualified name. Note that none of this would have happened if the coder had followed the convention that structs have capitalized names, `Eg`, and variables have lower-case ones, `eg.*

```java
package obscuring;

struct eg {
    static def ow()= 1;
    static struct Bite {
```
Due to obscuring, it may be impossible to refer to a type or a package via a simple name in some circumstances. Obscuring does not block qualified names.

### 6.1.4 Ambiguity and Disambiguation

Neither simple nor qualified names are necessarily unique. There can be, in general, many entities that have the same name. This is perfectly ordinary, and, when done well, considered good programming practice. Various forms of *disambiguation* are used to tell which entity is meant by a given name; e.g., methods with the same name may be disambiguated by the types of their arguments ([§8.12](#)).

**Example:** In the following example, there are three static methods with qualified name `DisambEx.Example.m`; they can be disambiguated by their different arguments. Inside the body of the third, the simple name `i` refers to both the `Long` formal of `m`, and to the static method `DisambEx.Example.i`.

```scala
package DisambEx;
class Example {
  static def m() = 1;
  static def m(Boolean) = 2;
  static def i() = 3;
  static def m(i:Long) {
    if (i > 10) {
      return i() + 1;
    }
    return i;
  }
  static def example() {
    assert m() == 1;
    assert m(true) == 2;
    assert m(3) == 3;
    assert m(20) == 4;
  }
}
```
6.2 Access Control

X10 allows programmers access control, that is, the ability to determine statically where identifiers of most sorts are visible. In particular, X10 allows information hiding, wherein certain data can be accessed from only limited parts of the program.

There are four access control modes: public, protected, private and uninflected package-specific scopes, much like those of Java. Most things can be public or private; a few things (e.g., class members) can also be protected or package-scoped.

Accessibility of one X10 entity (package, container, member, etc.) from within a package or container is defined as follows:

- Packages are always accessible.
- If a container $C$ is public, and, if it is inside of another container $D$, container $D$ is accessible, then $C$ is accessible.
- A member $m$ of a container $C$ is accessible from within another container $E$ if $C$ is accessible, and:
  - $m$ is declared public; or
  - $C$ is an interface; or
  - $m$ is declared protected, and either the access is from within the same package that $C$ is defined in, or from within the body of a subclass of $C$ (but see §6.2.1 for some fine points); or
  - $m$ is declared private, and the access is from within the top-level class which contains the definition of $C$ — which may be $C$ itself, or, if $C$ is a nested container, an outer class around $C$; or
  - $m$ has no explicit class declaration (hence using the implicit “package”-level access control), and the access occurs from the same package that $C$ is declared in.

### 6.2.1 Details of protected

protected access has a few fine points. Within the body of a subclass $D$ of the class $C$ containing the definition of a protected member $m$,

- An access $e.fld$ to a field, or $e.m(...)$ to a method, is permitted precisely when the type of $e$ is either $D$ or a subtype of $D$. For example, the access to `that.f` in the following code is acceptable, but the access to `xhax.f` is not.

```java
class C {
    protected var f : Long = 0;
}
class X extends C {}
```
class D extends C {
    def usef(that:D, xhax:X) {
        this.f += that.f;
        // ERROR: this.f += xhax.f;
    }
}

Limitation: The X10 compiler improperly allows access to xhax – as, indeed, some Java compilers do, despite Java having the analogous rule. The compiler allows you to do everything the spec says and a bit more.

- An access through a qualified name Q.N is permitted precisely when the type of Q is D or a subtype of D.

Qualified access to a protected constructor is subtle. Let C be a class with a protected constructor c, and let S be the innermost class containing a use u of c. There are three cases for u:

- Superclass construction invocations, super(...) or E.super(...), are permitted.
- Anonymous class instance creations, of the forms new C(...){...} and E.new C(...){...}, are permitted.
- No other accesses are permitted.

6.3 Packages

A package is a named collection of top-level type declarations, viz., class, interface, and struct declarations. Package names are sequences of identifiers, like x10.lang and com.ibm.museum. The multiple names are simply a convenience, though there is a tenuous relationship between packages a, a.b, and a.c. Packages can be accessed by name from anywhere: a package may contain private elements, but may not itself be private.

Packages and protection modifiers determine which top-level names can be used where. Only the public members of package pack.age can be accessed outside of pack.age itself.

package pack.age;
class Deal {
    public def make() {}
}
public class Stimulus {
    private def taxCut() = true;
    protected def benefits() = true;
The class `Stimulus` can be referred to from anywhere outside of `pack.age` by its full name of `pack.age.Stimulus`, or can be imported and referred to simply as `Stimulus`. The public `jobCreation()` method of a `Stimulus` can be referred to from anywhere as well; the other methods have smaller visibility. The non-public class `Deal` cannot be used from outside of `pack.age`.

### 6.3.1 Name Collisions

It is a static error for a package to have two members with the same name. For example, package `pack.age` cannot define two classes both named `Crash`, nor a class and an interface with that name.

Furthermore, `pack.age` cannot define a member `Crash` if there is another package named `pack.age.Crash`, nor vice-versa. (This prohibition is the only actual relationship between the two packages.) This prevents the ambiguity of whether `pack.age.Crash` refers to the class or the package. Note that the naming convention that package names are lower-case and package members are capitalized prevents such collisions.

### 6.4 import Declarations

Any public member of a package can be referred to from anywhere through a fully-qualified name: `pack.age.Stimulus`.

Often, this is too awkward. X10 has two ways to allow code outside of a class to refer to the class by its short name (`Stimulus`): single-type imports and on-demand imports. Imports of either kind appear at the start of the file, immediately after the `package` directive if there is one; their scope is the whole file.

#### 6.4.1 Single-Type Import

The declaration `import TypeName;` imports a single type into the current namespace. The type it imports must be a fully-qualified name of an extant type, and it must either be in the same package (in which case the `import` is redundant) or be declared public.

Furthermore, when importing `pack.age.T`, there must not be another type named `T` at that point: neither a `T` declared in `pack.age`, nor a `inst.ant.T` imported from some other package.

The declaration `import E.n;`, appearing in file `f` of a package named `P`, shadows the following types named `n` when they appear in `f`:
• Top-level types named \texttt{n} appearing in other files of \texttt{P}, and
• Types named \texttt{n} imported by automatic imports (§6.4.2) in \texttt{f}.

### 6.4.2 Automatic Import

The automatic import \texttt{import pack.age.\*;}, loosely, imports all the public members of \texttt{pack.age}. In fact, it does so somewhat carefully, avoiding certain errors that could occur if it were done naively. Types defined in the current package, and those imported by single-type imports, shadow those imported by automatic imports. If two automatic imports provide the same short name \texttt{n}, it is an error to use \texttt{n} – but it is not an error if no conflicting name is ever used. Names automatically imported never shadow any other names.

### 6.4.3 Implicit Imports

The package \texttt{x10.lang} is automatically imported in all files without need for further specification. Furthermore, the public static members of the class named \texttt{_} in \texttt{x10.lang} are imported everywhere as well. This provides a number of aliases, such as \texttt{Console} and \texttt{int} for \texttt{x10.io.Console} and \texttt{Int}.

### 6.5 Conventions on Type Names

\[
\text{TypeName} ::= \text{Id} \quad (20.172) \\
| \quad \text{TypeName} . \text{Id} \\
\text{PackageName} ::= \text{Id} \quad (20.128) \\
| \quad \text{PackageName} . \text{Id} \\
\]

While not enforced by the compiler, classes and interfaces in the X10 library follow the following naming conventions. Names of types—including classes, type parameters, and types specified by type definitions—are in CamelCase and begin with an uppercase letter. (Type variables are often single capital letters, such as \texttt{T}.) For backward compatibility with languages such as C and Java, type definitions are provided to allow primitive types such as \texttt{int} and \texttt{boolean} to be written in lowercase. Names of methods, fields, value properties, and packages are in camelCase and begin with a lowercase letter. Names of \texttt{static \ val} fields are in all uppercase with words separated by \_’s.
7 Interfaces

An interface specifies signatures for zero or more public methods, property methods, static vals, classes, structs, interfaces, types and an invariant.

The following puny example illustrates all these features:

```java
interface Pushable{prio() != 0} {
    def push(): void;
    static val MAX_PRIO = 100;
    abstract class Pushedness{}
    struct Pushy{}
    interface Pushing{}
    static type Shove = Long;
    property text():String;
    property prio():Long;
}

class MessageButton(text:String) implements Pushable{self.prio()==Pushable.MAX_PRIO} {
    public def push() {
        x10.io.Console.OUT.println(text + " pushed");
    }
    public property text() = text;
    public property prio() = Pushable.MAX_PRIO;
}
```

*Pushable* defines two property methods, one normal method, and a static value. It also establishes an invariant, that `prio() != 0`. *MessageButton* implements a constrained version of *Pushable*, viz. one with maximum priority. It defines the `push()` method given in the interface, as a public method—interface methods are implicitly public.

**Limitation:** X10 may not always detect that type invariants of interfaces are satisfied, even when they obviously are.

A container—a class or struct—can *implement* an interface, typically by having all the methods and property methods that the interface requires, and by providing a suitable implements clause in its definition.
A variable may be declared to be of interface type. Such a variable has all the property and normal methods declared (directly or indirectly) by the interface; nothing else is statically available. Values of any concrete type which implement the interface may be stored in the variable.

**Example:** The following code puts two quite different objects into the variable `star`, both of which satisfy the interface `Star`.

```java
interface Star { def rise():void; }
class AlphaCentauri implements Star {
    public def rise() {}
}
class ElvisPresley implements Star {
    public def rise() {}
}
class Example {
    static def example() {
        var star : Star;
        star = new AlphaCentauri();
        star.rise();
        star = new ElvisPresley();
        star.rise();
    }
}
```

An interface may extend several interfaces, giving X10 a large fraction of the power of multiple inheritance at a tiny fraction of the cost.

**Example:**

```java
interface Star{}
interface Dog{}
class Sirius implements Dog, Star{}
class Lassie implements Dog, Star{}
```
7.1 Interface Syntax

\[
\text{InterfaceDecln} := \text{Mods}^? \text{ interface Id TypeParamsI}^? \text{ Properties}^? \text{ Guard}^? \text{ ExtendsInterfaces}^? \text{ InterfaceBody} \tag{20.99}
\]

\[
\text{TypeParamsI} := [ \text{TypeParamIList} ] \tag{20.177}
\]

\[
\text{Guard} := \text{DepParams} \tag{20.83}
\]

\[
\text{ExtendsInterfaces} := \text{extends Type} \tag{20.66}
\]

\[
\text{ExtendsInterfaces} := \text{ExtendsInterfaces}, \text{Type} \tag{20.66}
\]

\[
\text{InterfaceBody} := \{ \text{InterfaceMemberDeclns} \} \tag{20.98}
\]

\[
\text{InterfaceMemberDecln} := \text{MethodDecln} \tag{20.100}
\]

The invariant associated with an interface is the conjunction of the invariants associated with its superinterfaces and the invariant defined at the interface.

A class \(C\) implements an interface \(I\) if \(I\), or a subtype of \(I\), appears in the implements list of \(C\). In this case, \(C\) implicitly gets all the methods and property methods of \(I\), as abstract public methods. If \(C\) does not declare them explicitly, then they are abstract, and \(C\) must be abstract as well. If \(C\) does declare them all, \(C\) may be concrete.

If \(C\) implements \(I\), then the class invariant \((\text{§ 8.9})\) for \(C\), \(\text{inv}(C)\), implies the class invariant for \(I\), \(\text{inv}(I)\). That is, if the interface \(I\) specifies some requirement, then every class \(C\) that implements it satisfies that requirement.

7.2 Access to Members

All interface members are public, whether or not they are declared public. There is little purpose to non-public methods of an interface; they would specify that implementing classes and structs have methods that cannot be seen.

7.3 Member Specification

An interface can specify that all containers implementing it must have certain instance methods. It cannot require constructors or static methods, though.

Example: The Stat interface requires that its implementers provide an ick method. It can’t insist that implementations provide a static method like \text{meth}, or a nullary constructor.

\[
\text{interface Stat} \{
\text{def ick}():\text{void};
\}
\]
7.4 Property Methods

An interface may declare property methods. All non-abstract containers implementing such an interface must provide all the property methods specified.

7.5 Field Definitions

An interface may declare a val field, with a value. This field is implicitly public static val. In particular, it is not an instance field.

```
interface KnowsPi {
    PI = 3.14159265358;
}
```

Classes and structs implementing such an interface get the interface’s fields as public static fields. Unlike methods, there is no need for the implementing class to declare them.

```
class Circle implements KnowsPi {
    static def area(r:Double) = PI * r * r;
}
```

```
class UsesPi {
    def circumf(r:Double) = 2 * r * KnowsPi.PI;
}
```

7.5.1 Fine Points of Fields

If two parent interfaces give different static fields of the same name, those fields must be referred to by qualified names.

```
interface E1 {static val a = 1;}
interface E2 {static val a = 2;}
interface E3 extends E1, E2{}
```
7.6. GENERIC INTERFACES

```scala
class Example implements E3 {
    def example() = E1.a + E2.a;
}
```

If the same field `a` is inherited through many paths, there is no need to disambiguate it:

```scala
interface I1 { static val a = 1;}
interface I2 extends I1 {}
interface I3 extends I1 {}
interface I4 extends I2, I3 {}
class Example implements I4 {
    def example() = a;
}
```

The initializer of a field in an interface may be any expression. It is evaluated under the same rules as a static field of a class.

**Example:** In this example, a class `TheOne` is defined, with an inner interface `WelshOrFrench`, whose field `UN` (named in either Welsh or French) has value 1. Note that `WelshOrFrench` does not define any methods, so it can be trivially added to the `implements` clause of any class, as it is for `Onesome`. This allows the body of `Onesome` to use `UN` through an unqualified name, as is done in `example()`.

```scala
class TheOne {
    static val ONE = 1;
    interface WelshOrFrench {
        val UN = 1;
    }
    static class Onesome implements WelshOrFrench {
        static def example() {
            assert UN == ONE;
        }
    }
}
```

### 7.6 Generic Interfaces

Interfaces, like classes and structs, can have type parameters. The discussion of generics in §4.3 applies to interfaces, without modification.

**Example:**

```scala
```
7.7 Interface Inheritance

The *direct superinterfaces* of a non-generic interface \( I \) are the interfaces (if any) mentioned in the *extends* clause of \( I \)'s definition. If \( I \) is generic, the direct superinterfaces are of an instantiation of \( I \) are the corresponding instantiations of those interfaces. A *superinterface* of \( I \) is either \( I \) itself, or a direct superinterface of a superinterface of \( I \), and similarly for generic interfaces.

\( I \) inherits the members of all of its superinterfaces. Any class or struct that has \( I \) in its *implements* clause also implements all of \( I \)'s superinterfaces.

Classes and structs may be declared to implement multiple interfaces. Semantically, the interface type is the set of all objects that are instances of classes or structs that implement the interface. A class or struct implements an interface if it is declared to and if it concretely or abstractly implements all the methods and properties defined in the interface. For example, \( \text{Kim} \) implements \( \text{Person} \), and hence \( \text{Named} \) and \( \text{Mobile} \).

It would be a static error if \( \text{Kim} \) had no *name* method, unless \( \text{Kim} \) were also declared abstract.

```scala
class Kim implements Person {
    var pos : Long = 0;
    public def name() = "Kim (" + pos + ")";
    public def move(dPos:Long) { pos += dPos; }
}
```

7.8 Members of an Interface

The members of an interface \( I \) are the union of the following sets:

1. All of the members appearing in \( I \)'s declaration;
2. All the members of its direct super-interfaces, except those which are hidden ([6.1.2]) by \( I \)
3. The members of *Any*.

Overriding for instances is defined as for classes, [8.4.8]
8 Classes

8.1 Principles of X10 Objects

8.1.1 Basic Design

Objects are instances of classes: the most common and most powerful sort of value in X10. The other kinds of values, structs and functions, are more specialized.

Classes are structured in a forest of single-inheritance code hierarchies. Like C++, but unlike Java, there is no single root class (e.g. java.lang.Object) that all classes inherit from. Classes may have any or all of these features:

- Implementing any number of interfaces;
- Static and instance val fields;
- Instance var fields;
- Static and instance methods;
- Constructors;
- Properties;
- Static and instance nested containers.
- Static type definitions

X10 objects (unlike Java objects) do not have locks associated with them. Programmers may use atomic blocks ([14.7]) for mutual exclusion and clocks ([15]) for sequencing multiple parallel operations.

An object exists in a single location: the place that it was created. One place cannot use or even directly refer to an object in a different place. A special type, GlobalRef[T], allows explicit cross-place references.

The basic operations on objects are:
• Construction ([8.11]). Objects are created, their var and val fields initialized, and other invariants established.

• Field access ([11.4]). The static, instance, and property fields of an object can be retrieved; var fields can be set.

• Method invocation ([11.6]). Static, instance, and property methods of an object can be invoked.

• Casting ([11.22]) and instance testing with instanceof ([11.24]) Objects can be cast or type-tested.

• The equality operators == and !=. Objects can be compared for equality with the == operation. This checks object identity: two objects are == iff they are the same object.

8.1.2 Class Declaration Syntax

The class declaration has a list of type parameters, a list of properties, a constraint (the class invariant), zero or one superclass, zero or more interfaces that it implements, and a class body containing the definition of fields, properties, methods, and member types. Each such declaration introduces a class type ([4.2]).

```plaintext
ClassDecln ::= Mods^2 class Id TypeParamsI^2 Properties^2 Guard^2 Super^2 Interfaces^2 (20.34)

TypeParamsI ::= [ TypeParamIList ] (20.177)
TypeParamIList ::= TypeParam (20.174)
                  | TypeParamIList , TypeParam
                  | TypeParamIList ,

Props ::= ( PropList ) (20.142)
PropList ::= Prop (20.140)
            | PropList , Prop

Prop ::= Annotations^2 Id ResultType (20.139)
Guard ::= DepParams (20.133)
Super ::= extends ClassType (20.156)
Interfaces ::= implements InterfaceTypeList (20.103)
InterfaceTypeList ::= Type (20.102)
                    | InterfaceTypeList , Type

ClassBody ::= { ClassMemberDeclns^2 } (20.33)
ClassMemberDeclns ::= ClassMemberDecln (20.36)
                     | ClassMemberDeclns ClassMemberDecln

ClassMemberDecln ::= InterfaceMemberDecln (20.35)
                    | CtorDecln
```
8.2 Fields

Objects may have *instance fields*, or simply *fields* (called “instance variables” in C++ and Smalltalk, and “slots” in CLOS): places to store data that is pertinent to the object. Fields, like variables, may be mutable (var) or immutable (val).

A class may have *static fields*, which store data pertinent to the entire class of objects. See [§8.6](#) for more information. Because of its emphasis on safe concurrency, X10 requires static fields to be immutable (val).

No two fields of the same class may have the same name. A field may have the same name as a method, although for fields of functional type there is a subtlety ([§8.12.4](#)).

8.2.1 Field Initialization

Fields may be given values via *field initialization expressions*: val \( f_1 = E \); and var \( f_2 : \text{Long} = F \); Other fields of this may be referenced, but only those that precede the field being initialized.

**Example:** The following is correct, but would not be if the fields were reversed:

```scala
class Fld{
  val a = 1;
  val b = 2+a;
}
```

8.2.2 Field hiding

A subclass that defines a field \( f \) hides any field \( f \) declared in a superclass, regardless of their types. The superclass field \( f \) may be accessed within the body of the subclass via the reference `super.f`.

With inner classes, it is occasionally necessary to write `Cls.super.f` to get at a hidden field \( f \) of an outer class `Cls`.

**Example:** The \( f \) field in Sub hides the \( f \) field in Super The `superf` method provides access to the \( f \) field in Super:

```scala
class Super{
  public val f = 1;
}
class Sub extends Super {
  val f = true;
  def superf() : Long = super.f; // 1
}
```

**Example:** Hidden fields of outer classes can be accessed by suitable forms:
class A {
    val f = 3;
}
class B extends A {
    val f = 4;
    class C extends B {
        // C is both a subclass and inner class of B
        val f = 5;
        def example() {
            assert f == 5 : "field of C";
            assert super.f == 4 : "field of superclass";
            assert B.this.f == 4 : "field of outer instance";
            assert B.super.f == 3 : "super.f of outer instance";
        }
    }
}

8.2.3 Field qualifiers

The behavior of a field may be changed by a field qualifier, such as static or transient.

static qualifier

A val field may be declared to be static, as described in § 8.2.

transient Qualifier

A field may be declared to be transient. Transient fields are excluded from the deep copying that happens when information is sent from place to place in an at statement. The value of a transient field of a copied object is the default value of its type, regardless of the value of the field in the original. If the type of a field has no default value, it cannot be marked transient.

class Trans {
    val copied = "copied";
    transient var transy : String = "a very long string";
    def example() {
        at (here) { // causes copying of 'this'
            assert(this.copyed.equals("copied"));
            assert(this.transy == null);
        }
    }
}
8.3. Properties

The properties of an object (or struct) are a restricted form of public val fields. For example, every array has a rank telling how many subscripts it takes. User-defined classes can have whatever properties are desired.

Properties differ from public val fields in a few ways:

1. Property references are allowed on self in constraints: self.prop. Field references are not.
2. Properties are in scope for all instance initialization expressions. val fields are not.
3. The graph of values reachable from a given object by following only property links is acyclic. Conversely, it is possible (and routine) for two objects to point to each other with val fields.
4. Properties are declared in the class header; val fields are defined in the class body.
5. Properties are set in constructors by a property statement. val fields are set by assignment.

Properties are defined in parentheses, after the name of the class. They are given values by the property command in constructors.

Example: Proper has a single property, t. new Proper(4) creates a Proper object with t==4.

```scala
class Proper(t:Long) {
  def this(t:Long) {property(t);}
}
```

It is a static error for a class defining a property x: T to have a subclass class that defines a property or a field with the name x.

A property x:T induces a field with the same name and type, as if defined with:

```scala
public val x : T;
```

Properties are initialized in a constructor by the invocation of a special property statement. The requirement to use the property statement means that all properties must be given values at the same time: a container either has its properties or it does not.

```scala
property(e1,..., en);
```

\*In many cases, a val field can be upgraded to a property, which entails no compile-time or runtime cost. Some cannot be, e.g., in cases where cyclic structures of val fields are required.
The number and types of arguments to the `property` statement must match the number and types of the properties in the class declaration, in order. Every constructor of a class with properties must invoke `property(...)` precisely once; it is a static error if X10 cannot prove that this holds.

By construction, the graph whose nodes are values and whose edges are properties is acyclic. E.g., there cannot be values `a` and `b` with properties `c` and `d` such that `a.c == b` and `b.d == a`.

Example:

```scala
class Proper(a:Long, b:String) {
  def this(a:Long, b:String) {
    property(a, b);
  }
  def this(z:Long) {
    val theA = z+5;
    val theB = "X"+z;
    property(theA, theB);
  }
  static def example() {
    val p = new Proper(1, "one");
    assert p.a == 1 && p.b.equals("one");
    val q = new Proper(10);
    assert q.a == 15 && q.b.equals("X10");
  }
}
```

### 8.3.1 Properties and Field Initialization

Fields with explicit initializers are evaluated immediately after the `property` command, and all properties are in scope when initializers are evaluated.

**Example:** Class `Init` initializes the field `a` to be a rail of `n` elements, where `n` is a property. When new `Init(4)` is executed, the constructor first sets `n` to 4 via the `property` statement, and then initializes `a` to a 4-element rail.

However, `Outit` uses a field rather than a property for `n`. If the `ERROR` line were present, it would not compile. `n` has not been definitely assigned (§19) at this point, and `n` has not been given its value, so `a` cannot be computed. (If one insisted that `n` be a property, `a` would have to be initialized in the constructor, rather than by an initialization expression.)

```scala
class Init(n:Long) {
  val a = new Rail[String](n, "");
  def this(n:Long) { property(n); }
}
class Outit {
```
8.4. METHODS

```scala
val n : Long;
//ERROR: val a = new Rail[String](n, "");
def this(m:Long) { this.n = m; }
```

8.3.2 Properties and Fields

A container with a property named \( p \), or a nullary property method named \( p() \), cannot have a field named \( p \) — either defined in that container, or inherited from a superclass.

8.3.3 Acyclicity of Properties

X10 has certain restrictions that, ultimately, require that properties are simpler than their containers. For example, `class A(a:A){}` is not allowed. Formally, this requirement is that there is a total order \( \preceq \) on all classes and structs such that, if \( A \) extends \( B \), then \( A \prec B \), and if \( A \) has a property of type \( B \), then \( A \prec B \), where \( A \prec B \) means \( A \preceq B \) and \( A \neq B \). For example, the preceding class \( A \) is ruled out because we would need \( A \prec A \), which violates the definition of \( \prec \). The programmer need not (and cannot) specify \( \preceq \), and rarely need worry about its existence.

Similarly, the type of a property may not simply be a type parameter. For example, `class A[X](x:X){}` is illegal.

8.4 Methods

As is common in object-oriented languages, objects can have methods, of two sorts. **Static methods** are functions, conceptually associated with a class and defined in its namespace. **Instance methods** are parameterized code bodies associated with an instance of the class, which execute with convenient access to that instance’s fields.

Each method has a **signature**, telling what arguments it accepts, what type it returns, and what precondition it requires. Method definitions may be overridden by subclasses; the overriding definition may have a declared return type that is a subtype of the return type of the definition being overridden. Multiple methods with the same name but different signatures may be provided on a class (called “overloading” or “ad hoc polymorphism”). Methods may be declared public, private, protected, or given default package-level access rights.
A formal parameter may have a val or var modifier; val is the default. The body of the method is executed in an environment in which each formal parameter corresponds to a local variable (var iff the formal parameter is var) and is initialized with the value of the actual parameter.
8.4. METHODS

8.4.1 Forms of Method Definition

There are several syntactic forms for defining methods. The forms that include a block, such as `def m() {S}`, allow an arbitrary block. These forms can define a `void` method, which does not return a value.

The forms that include an expression, such as `def m() = E`, require a syntactically and semantically valid expression. These forms cannot define a `void` method, because expressions cannot be `void`.

There are no other semantic differences between the two forms.

8.4.2 Method Return Types

A method with an explicit return type returns values of that type. A method without an explicit return type is given a return type by type inference. A call to a method has type given by substituting information about the actual val parameters for the formals.

Example:

In the example below, `met1` has an explicit return type `Ret{n==a}`. `met2` does not, so its return type is computed, also to be `Ret{n==a}`, because that’s what the implicitly-defined constructor returns.

`use3` requires that its argument have `n==3`. example shows that both `met1` and `met2` can be used to produce such an object. In both cases, the actual argument 3 is substituted for the formal argument `a` in the return type expression for the method `Ret{n==a}`, giving the type `Ret{n==3}` as required by `use3`.

```scala
class Ret(n:Long) {
  static def met1(a:Long) : Ret{n==a} = new Ret(a);
  static def met2(a:Long) = new Ret(a);
  static def use3(Ret{n==3}) {} 
  static def example() {
    use3(met1(3));
    use3(met2(3));
  }
}
```

8.4.3 Throws Clause

The `throws` clause indicates what checked exceptions may be raised during the execution of the method and are not handled by catch blocks within the method. If a checked exception may escape from the method, then it must be by a subtype of one of the types listed in the `throws` clause of the method. Checked exceptions are defined to be any subclass of `x10.lang.CheckedThrowable` that are not also subclasses of either `x10.lang.Exception` or `x10.lang.Error`. 
If a method is implementing an interface or overriding a superclass method the set of types represented by its throws clause must by a (potentially improper) subset of the types of the throws clause of the method it is overriding.

8.4.4 Final Methods

An instance method may be given the final qualifier. final methods may not be overridden.

8.4.5 Generic Instance Methods

Limitation: In X10, an instance method may be generic:

```scala
class Example {
    def example[T](t:T) = "I like " + t;
}
```

However, the C++ back end does not currently support generic virtual instance methods like example. It does allow generic instance methods which are final or private, and it does allow generic static methods.

8.4.6 Method Guards

Often, a method will only make sense to invoke under certain statically-determinable conditions. These conditions may be expressed as a guard on the method.

Example: For example, example(x) is only well-defined when x != null, as null.toString() throws a null pointer exception, and returns nothing:

```scala
class Example {
    var f : String = ""
    def setF(x:Any){x != null} : void {
        this.f = x.toString();
    }
}
```

(We could have used a constrained type Any{self!=null} for x instead; in most cases it is a matter of personal preference or convenience of expression which one to use.)

The requirement of having a method guard is that callers must demonstrate to the X10 compiler and/or runtime that the guard is satisfied. With the STATIC_CHECKS compiler option in force ([C.1.3], this is checked at compile time, and there is no runtime cost. Indeed, this code can be more efficient than usual, as it is statically provable that x != null.
8.4. METHODS

When STATIC_CHECKS is not in force, dynamic checks are generated as needed; method guards are checked at runtime. This is potentially more expensive, but may be more convenient.

**Example:** The following code fragment contains a line which will not compile with STATIC_CHECKS on (assuming the guarded example method above). (X10’s type system does not attempt to propagate information from ifs.) It will compile with STATIC_CHECKS off, but it may insert an extra null-test for x.

```java
def exam(e:Example, x:Any) {
    if (x != null)
        e.example(x as Any{x != null});
    // If STATIC_CHECKS is in force:
    // ERROR: if (x != null) e.example(x);
}
```

The guard \{c\} in a guarded method `def m(){c} = E;` specifies a constraint c on the properties of the class C on which the method is being defined. The method, in effect, only exists for those instances of C which satisfy c. It is illegal for code to invoke the method on objects whose static type is not a subtype of C\{c\}.

Specifically: the compiler checks that every method invocation `o.m(e_1, ..., e_n)` is type correct. Each argument e_i must have a static type S_i that is a subtype of the declared type T_i for the i\textsuperscript{th} argument of the method, and the conjunction of the constraints on the static types of the arguments must entail the guard in the parameter list of the method.

The compiler checks that in every method invocation `o.m(e_1, ..., e_n)` the static type of o, S, is a subtype of C\{c\}, where the method is defined in class C and the guard for m is equivalent to c.

Finally, if the declared return type of the method is D\{d\}, the return type computed for the call is D\{a: S; x_1: S_1; ...; x_n: S_n; d[a/this]\}, where a is a new variable that does not occur in d, S, S_1, ..., S_n, and x_1, ..., x_n are the formal parameters of the method.

**Limitation:** Using a reference to an outer class, Outer.this, in a constraint, is not supported.

### 8.4.7 Property methods

\[\text{PropMethodDecln ::= Mods}\? \text{property Id TypeParams}\? \text{Formals Guard}\? \text{Throws}\? (20.141)\]

Property methods are methods that can be evaluated in constraints, as properties can. They provide a means of abstraction over properties; e.g., interfaces can specify property methods that implementing containers must provide, but, just as they cannot specify ordinary fields, they cannot specify property fields. Property methods are very
limited in computing power: they must obey the same restrictions as constraint expressions. In particular, they cannot have side effects, or even much code in their bodies.

Example: The eq() method below tells if the x and y properties are equal; the is(z) method tells if they are both equal to z. The eq and is property methods are used in types in the example method.

```scala
class Example(x:Long, y:Long) {
  def this(x:Long, y:Long) { property(x,y); }
  property eq() = (x==y);
  property is(z:Long) = x==z && y==z;
  def example( a : Example{eq()}, b : Example{is(3)} ) {}
}
```

A property method declared in a class must have a body and must not be void. The body of the method must consist of only a single return statement with an expression, or a single expression. It is a static error if the expression cannot be represented in the constraint system. Property methods may be abstract in abstract classes, and may be specified in interfaces, but are implicitly final in non-abstract classes.

The expression may contain invocations of other property methods. The compiler ensures that there are no circularities in property methods, so property method evaluations always terminate.

Property methods in classes are implicitly final; they cannot be overridden. It is a static error if a superclass has a property method with a given signature, and a subclass has a method or property method with the same signature. It is a static error if a superclass has a property with some name p, and a subclass has a nullary method of any kind (instance, static, or property) also named p.

A nullary property method definition may omit the def keyword. That is, the following are equivalent:

```scala
property def rail(): Boolean =
  rect && onePlace == here && zeroBased;
```
and

```scala
property rail(): Boolean =
  rect && onePlace == here && zeroBased;
```

Similarly, nullary property methods can be inspected in constraints without (). If ob's type has a property p, then ob.p is that property. Otherwise, if it has a nullary property method p(), ob.p is equivalent to ob.p(). As a consequence, if the type provides both a property p and a nullary method p(), then the property can be accessed as ob.p and the method as ob.p().

---

2This only applies to nullary property methods, not nullary instance methods. Nullary property methods perform limited computations, have no side effects, and always return the same value, since they have to be expressed in the constraint sublanguage. In this sense, a nullary property method does not behave hugely different from a property. Indeed, a compilation scheme which cached the value of the property method would all but erase the distinction. Other methods may have more behavior, e.g., side effects, so we keep the () to make it clear that a method call is potentially complex.
w.rail, with either definition above, is equivalent to w.rail()

**Limitation of Property Methods**

**Limitation:** Currently, X10 forbids the use of property methods which have all the following features:

- they are abstract, and
- they have one or more arguments, and
- they appear as subterms in constraints.

Any two of these features may be combined, but the three together may not be.

**Example:** The constraint in example1 is concrete, not abstract. The constraint in example2 is nullary, and has no arguments. The constraint in example3 appears at the top level, rather than as a subterm (cf. the equality expressions A==B in the other examples). However, example4 combines all three features, and is not allowed.

```java
class Cls {
    property concrete(a:Long) = 7;
}
interface Inf {
    property nullary(): Long;
    property topLevel(z:Long): Boolean;
    property allThree(z:Long): Long;
}
class Example{
    def example1(Cls{self.concrete(3)==7}) = 1;
    def example2(Inf{self.nullary()==7}) = 2;
    def example3(Inf{self.topLevel(3)}) = 3;
    //ERROR: def example4(Inf{self.allThree(3)==7}) = "fails";
}
```

### 8.4.8 Method overloading, overriding, hiding, shadowing and obscuring

The definitions of method overloading, overriding, hiding, shadowing and obscuring in X10 are familiar from languages such as Java, modulo the following considerations motivated by type parameters and dependent types.

Two or more methods of a class or interface may have the same name if they have a different number of type parameters, or they have formal parameters of different constraint-erased types (in some instantiation of the generic parameters).

**Example:** The following overloading of m is unproblematic.
class Mful{
  def m() = 1;
  def m[T]() = 2;
  def m(x:Long) = 3;
  def m[T](x:Long) = 4;
}

A class definition may include methods which are ambiguous in some generic instantiation. (It is a compile-time error if the methods are ambiguous in every generic instantiation, but excluding class definitions which are ambiguous in some instantiation would exclude useful cases.) It is a compile-time error to use an ambiguous method call.

**Example:** The following class definition is acceptable. However, the marked method calls are ambiguous, and hence not acceptable.

class Two[T,U]{
  def m(x:T)=1;
  def m(x:Long)=2;
  def m[X](x:X)=3;
  def m(x:U)=4;
  static def example() {
    val t12 = new Two[Long, Any]();
    // ERROR: t12.m(2);
    val t13 = new Two[String, Any]();
    t13.m("ferret");
    val t14 = new Two[Boolean, Boolean]();
    // ERROR: t14.m(true);
  }
}

The call t12.m(2) could refer to either the 1 or 2 definition of m, so it is not allowed. The call t14.m(true) could refer to either the 1 or 4 definition, so it, too, is not allowed.

The call t13.m("ferret") refers only to the 1 definition. If the 1 definition were absent, type argument inference would make it refer to the 3 definition. However, X10 will choose a fully-specified call if there is one, before trying type inference, so this call unambiguously refers to 1.

X10 v2.4 does not permit overloading based on constraints. That is, the following is not legal, although either method definition individually is legal:

def n(x:Long){x==1} = "one";
def n(x:Long){x!=1} = "not";

The definition of a method declaration m₁ “having the same signature as” a method declaration m₂ involves identity of types.
The constraint erasure of a type \( T \), \( ce(T) \), is obtained by removing all the constraints outside of functions in \( T \), specifically:

\[
    \begin{align*}
    ce(T) &= T \text{ if } T \text{ is a container or interface} \\ 
    ce(T[c]) &= ce(T) \\ 
    ce(T[S_1, \ldots, S_n]) &= ce(T)[ce(S_1), \ldots, ce(S_n)] \\ 
    ce((S_1, \ldots, S_n) \Rightarrow T) &= (ce(S_1), \ldots, ce(S_n)) \Rightarrow ce(T)
    \end{align*}
\]

Two methods are said to have erasure equivalent signatures if (a) they have the same number of type parameters, (b) they have the same number of formal (value) parameters, and (c) for each formal parameter the constraint erasure of its types are erasure equivalent. It is a compile-time error for there to be two methods with the same name and erasure equivalent signatures in a class (either defined in that class or in a superclass), unless the signatures are identical (without erasures) and one of the methods is defined in a superclass (in which case the superclass’s method is overridden by the subclass’s, and the subclass’s method’s return type must be a subtype of the superclass’s method’s return type).

In addition, the guard of an overridden method must entail the guard of the overriding method. This ensures that any virtual call to the method satisfies the guard of the callee.

**Example:** In the following example, the call to \( s.recip(3) \) in \( example() \) will invoke \( Sub.recip(n) \). The call is legitimate because \( Super.recip \)'s guard, \( n \neq 0 \), is satisfied by \( 3 \). The guard on \( Sub.recip(n) \) is simply \( true \), which is also satisfied. However, if we had used the ERROR line’s definition, the guard on \( Sub.recip(n) \) would be \( n \neq 0, n \neq 3 \), which is not satisfied by \( 3 \), so – despite the call statically type-checking – at runtime the call would violate its guard and (in this case) throw an exception.

```scala
class Super {
    def recip(n:Long){n != 0} = 1.0/n;
}
class Sub extends Super{
    //ERROR: def recip(n:Long){n != 0, n != 3} = 1.0/(n * (n-3));
    def recip(m:Long){true} = 1.0/m;
}
class Example{
    static def example() {
        val s : Super = new Sub();
        s.recip(3);
    }
}
```

If a class \( C \) overrides a method of a class or interface \( B \), the guard of the method in \( B \) must entail the guard of the method in \( C \).

A class \( C \) inherits from its direct superclass and superinterfaces all their methods visible according to the access modifiers of the superclass/superinterfaces that are not hidden
or overridden. A method $M_1$ in a class $C$ overrides a method $M_2$ in a superclass $D$ if $M_1$ and $M_2$ have erasedly equivalent signatures. Methods are overridden on a signature-by-signature basis. It is a compile-time error if an instance method overrides a static method. (But is it permitted for an instance field to hide a static field; that’s hiding (§8.2.2), not overriding, and hence totally different.)

### 8.5 Constructors

Instances of classes are created by the new expression:

$$
ObCreationExp ::= \text{new } \text{TypeName TypeArgs}^? ( \text{ArgumentList}^? ) \text{ClassBody}^? (20.126) \\
| \text{Primary} . \text{new} \text{Id TypeArgs}^? ( \text{ArgumentList}^? ) \text{ClassBody}^?
| \text{FullyQualifiedName} . \text{new} \text{Id TypeArgs}^? ( \text{ArgumentList}^? ) \text{ClassBody}^?
$$

This constructs a new object, and calls some code, called a constructor, to initialize the newly-created object properly.

Constructors are defined like methods, except that they must be named this and ordinary methods may not be. The content of a constructor body has certain capabilities (e.g., val fields of the object may be initialized) and certain restrictions (e.g., most methods cannot be called); see [§8.11] for the details.

**Example:**

*The following class provides two constructors. The unary constructor def this(b : Long) allows initialization of the a field to an arbitrary value. The nullary constructor def this() gives it a default value of 10. The example method illustrates both of these calls.*

```scala
class C {
  public val a : Long;
  def this(b : Long) { a = b; }
  def this() { a = 10; }
  static def example() {
    val two = new C(2);
    assert two.a == 2;
    val ten = new C();
    assert ten.a == 10;
  }
}
```

### 8.5.1 Automatic Generation of Constructors

Classes that have no constructors written in the class declaration are automatically given a constructor which sets the class properties and does nothing else. If this automatically-generated constructor is not valid (e.g., if the class has val fields that
need to be initialized in a constructor, the class has no constructor, which is a static
error.

Example: The following class has no explicit constructor. Its implicit constructor is
def this(x:Long){property(x);} This implicit constructor is valid, and so is the
class.

class C(x:Long) {
  static def example() {
    val c : C = new C(4);
    assert c.x == 4;
  }
}

The following class has the same default constructor. However, that constructor does
not initialize d, and thus is invalid. This class does not compile; it needs an explicit
constructor.

// THIS CODE DOES NOT COMPIL e
class Cfail(x:Long) {
  val d: Long;
  static def example() {
    val wrong = new Cfail(40);
  }
}

8.5.2 Calling Other Constructors

The first statement of a constructor body may be a call of the form this(a,b,c) or
super(a,b,c). The former will execute the body of the matching constructor of the
current class; the latter, of the superclass. This allows a measure of abstraction in
constructor definitions; one may be defined in terms of another.

Example: The following class has two constructors. new Ctors(123) constructs a
new Ctors object with parameter 123. new Ctors() constructs one whose parameter
has a default value of 100:

class Ctors {
  public val a : Long;
  def this(a:Long) { this.a = a; }
  def this() { this(100); }
}

In the case of a class which implements operator () — or any other constructor and
application with the same signature — this can be ambiguous. If this() appears as
the first statement of a constructor body, it could, in principle, mean either a construc-
tor call or an operator evaluation. This ambiguity is resolved so that this() always
means the constructor invocation. If, for some reason, it is necessary to invoke an application operator as the first meaningful statement of a constructor, write the target of the application as (this), e.g., (this)(a,b);

\subsection*{8.5.3 Return Type of Constructor}

A constructor for class \( C \) may have a return type \( C\{c\} \). The return type specifies a constraint on the kind of object returned. It cannot change its \textit{class} — a constructor for class \( C \) always returns an instance of class \( C \). If no explicit return type is specified, the constructor’s return type is inferred.

\textbf{Example:} The constructor (A) below, having no explicit return type, has its return type inferred. \( n \) is set by the \textit{property} statement to 1, so the return type is inferred as \( \text{Ret}\{\text{self.n==1}\} \). The constructor (B) has \( \text{Ret}\{n==\text{self.n}\} \) as an explicit return type. The \textit{example()} code shows both of these in action.

```java
class Ret(n:Long) {
    def this() { property(1); } // (A)
    def this(n:Long) : Ret{n==self.n} { // (B)
        property(n);
    }
    static def typeIs[T](x:T){}
    static def example() {
        typeIs[Ret{self.n==1}](new Ret()); // uses (A)
        typeIs[Ret{self.n==3}](new Ret(3)); // uses (B)
    }
}
```

\section*{8.6 Static initialization}

Static fields in X10 are immutable and are guaranteed to be initialized before they are accessed. Static fields are initialized on a per-Place basis; thus an activity that reads a static field in two different Places may read different values for the content of the field in each Place. Static fields are not eagerly initialized, thus if a particular static field is not accessed in a given Place then the initializer expression for that field may not be evaluated in that Place.

When an activity running in a Place \( P \) attempts to read a static field \( F \) that has not yet been initialized in \( P \), then the activity will evaluate the initializer expression for \( F \) and store the resulting value in \( F \). It is guaranteed that at most one activity in each Place will attempt to evaluate the initializer expression for a given static field. If a second activity attempts to read \( F \) while the first activity is still executing the initializer expression the second activity will be suspended until the first activity finishes evaluating the initializer and stores the resulting value in \( F \).
8.6. STATIC INITIALIZATION

The initializer expression may directly or indirectly read other static fields in the program. If there is a cycle in the field initialization dependency graph for a set of static fields, then any activities accessing those fields may deadlock, which in turn may result in the program deadlocking.

If an exception is raised during the evaluation of a static field’s initializer expression, then the field is deemed uninitializable in that Place and any subsequent attempt to access the static field’s value by another activity in the Place will also result in an exception being raised. Failure to initialize a field in one Place does not impact the initialization status of the field in other Places.

8.6.1 Compatability with Prior Versions of X10

Previous versions of X10 eagerly initialized all static fields in the program at Place 0 and serialized the resulting values to all other Places before beginning execution of the user main function. It is possible to simulate these serialization semantics for specific static fields under the lazy per-Place initialization semantics by using the idiom below:

```java
// Pre X10 2.3 code
// expr evaluated once in Place 0 and resulting value
// serialized to all other places
public static val x:T = expr;

// X10 2.3 code when T haszero is false
private static val x_holder:Cell[T] =
    (here == Place.FIRST_PLACE) ? new Cell[T](expr): null;
public static val x:T = at (Place.FIRST_PLACE) x_holder();

// simpler X10 2.3 code when T haszero is true
private static val x_holder:T =
    (here == Place.FIRST_PLACE) ? expr : Zero.get[T]();
public static val x:T = at (Place.FIRST_PLACE) x_holder;
```

A slightly more complex variant of the above idiom in which the initializer expression for the public field conditionally does the `at` only when not executed at `Place.FIRST_PLACE` can be used to obtain exactly the same serialization behavior as the pre X10 v2.3 semantics. When necessary, eager initialization for specific static fields can be simulated by reading the static fields in main before executing the rest of the program.

3The current X10 runtime does not dynamically detect this situation. Future versions of X10 may be able to detect this and convert such a deadlock into the throwing of an `ExceptionInInitializer` exception.

4The implementation will make a best effort attempt to present stack trace information about the original cause of the exception in all subsequent raised exceptions.
8.7 User-Defined Operators

MethodDecln ::= MethMods def Id TypeParams? Formals Guard? Throws? HasResultType? MethodBody
| BinOpDecln
| PrefixOpDecln
| ApplyOpDecln
| SetOpDecln
| ConversionOpDecln
| KeywordOpDecln

It is often convenient to have methods named by symbols rather than words. For example, suppose that we wish to define a Poly class of polynomials – for the sake of illustration, single-variable polynomials with Long coefficients. It would be very nice to be able to manipulate these polynomials by the usual operations: + to add, * to multiply, – to subtract, and p(x) to compute the value of the polynomial at argument x. We would like to write code thus:

```java
public static def main(Rail[String]):void {
    val X = new Poly([0L,1L]);
    val t <: Poly = 7 * X + 6 * X * X;
    val u <: Poly = 3 + 5*X - 7*X*X;
    val v <: Poly = t * u - 1;
    for( i in -3 .. 3) {
        x10.io.Console.OUT.println(
            "" + i + " X:" + X(i) + " t:" + t(i) + " u:" + u(i) + " v:" + v(i)
        );
    }
}
```

Writing the same code with method calls, while possible, is far less elegant:

```java
public static def uglymain() {
    val X = new UglyPoly([0L,1L]);
    val t <: UglyPoly = X.mult(7).plus(
        X.mult(X).mult(X).mult(6));
    val u <: UglyPoly = const(3).plus(
        X.mult(5)).minus(X.mult(X).mult(7));
    val v <: UglyPoly = t.mult(u).minus(1);
    for( i in -3 .. 3) {
        x10.io.Console.OUT.println(
            "" + i + " X:" + X.apply(i) + " t:" + t.apply(i) + " u:" + u.apply(i) + " v:" + v.apply(i)
        );
    }
}
```
8.7. USER-DEFINED OPERATORS

The operator-using code can be written in X10, though a few variations are necessary to handle such exotic cases as 1+X.

Most X10 operators can be given definitions\(^5\) (However, && and || are only short-circuiting for Boolean expressions; user-defined versions of these operators have no special execution behavior.)

The user-definable operations are (in order of precedence):

class Trace(n:Long){
    public static operator !(f:Trace)
        = new Trace(10 * f.n + 1);
    public operator -this = new Trace (10 * this.n + 2);
}

\(^5\)Indeed, even for the standard types, these operators are defined in the library. Not even as basic an operation as integer addition is built into the language. Conversely, if you define a full-featured numeric type, it will have most of the privileges that the standard ones enjoy. The missing privileges are (1) literals; (2) * won’t track ranks, as it does for Regions; (3) && and || won’t short-circuit, as they do for Booleans, (4) the built-in notion of equality a==b will only coincide with the programmible notion a.equals(b), as they do for most library types, if coded that way; and (5) it is impossible to define an operation like String.+, which converts both its left and right arguments from any type. For example, a Polar type might have many representations for the origin, as radius 0 and any angle; these will be equals(), but will not be ==; whereas for the standard Complex type, the two equalities are the same.
static class Brace extends Trace{
    def this(n:Long) { super(n); }
    public operator -this = new Brace (10 * this.n + 3);
    static def example() {
        val t = new Trace(1);
        assert (!t).n == 11;
        assert (-t).n == 12 && (-t instanceof Trace);
        val b = new Brace(1);
        assert (!b).n == 11;
        assert (-b).n == 13 && (-b instanceof Brace);
    }
}

8.7.1 Binary Operators

Binary operators, illustrated by +, may be defined statically in a container A as:

    static operator (b:B) + (c:C) = ...;

Or, it may be defined as an instance operator by one of the forms:

    operator this + (b:B) = ...;
    operator (b:B) + this = ...;

Example:

Defining the sum \( P+Q \) of two polynomials looks much like a method definition. It uses the operator keyword instead of def, and this appears in the definition in the place that a Poly would appear in a use of the operator. So, operator this + (p:Poly) explains how to add this to a Poly value.

class Poly {
    public val coeff : Rail[Long];
    public def this(coeff: Rail[Long]) {
        this.coeff = coeff;
    }
    public def degree() = coeff.size-1;
    public def a(i:Long)
        = (i<0 || i>this.degree()) ? 0L : coeff(i);
    public operator this + (p:Poly) = new Poly(
        new Rail[Long](
            Math.max(this.coeff.size, p.coeff.size),
            (i:Long) => this.a(i) + p.a(i)
        ));
    // ...
}

The sum of a polynomial and an integer, \( P+3 \), looks like an overloaded method definition.
public operator this + (n : Long)
    = new Poly([n as Long]) + this;

However, we want to allow the sum of an integer and a polynomial as well: 3+P. It would be quite inconvenient to have to define this as a method on Long; changing Long is far outside of normal coding. So, we allow it as a method on Poly as well.

public operator (n : Long) + this
    = new Poly([n as Long]) + this;

Furthermore, it is sometimes convenient to express a binary operation as a static method on a class. The definition for the sum of two Polys could have been written:

public static operator (p:Poly) + (q:Poly) = new Poly(  
    new Rail[Long](
        Math.max(q.coeff.size, p.coeff.size),
        (i:Long) => q.a(i) + p.a(i)
    )
);  

When X10 attempts to typecheck a binary operator expression like P+Q, it first typechecks P and Q. Then, it looks for operator declarations for + in the types of P and Q. If there are none, it is a static error. If there is precisely one, that one will be used. If there are several, X10 looks for a best-matching operation, viz. one which does not require the operands to be converted to another type. For example, operator this + (n:Long) and operator this + (n:Int) both apply to p+in, because in can be converted from an Int to a Long. However, the Int version will be chosen because it does not require a conversion. If even the best-matching operation is not uniquely determined, the compiler will report a static error.

8.7.2 Unary Operators

Unary operators, illustrated by !, may be defined statically in container A as

    static operator !(x:A) = ...;

or as instance operators by:

    operator !this = ...;

The rules for typechecking a unary operation are the same as for methods; the complexities of binary operations are not needed.

Example:  The operator to negate a polynomial is:

    public operator - this = new Poly(  
        new Rail[Long](coeff.size, (i:Long) => -coeff(i))
    );
8.7.3 Type Conversions

Explicit type conversions, \( e \text{ as } A \), can be defined as operators on class \( A \), or on the container type of \( e \). These must be static operators.

To define an operator in class \( A \) (or `struct A`) converting values of type \( B \) into type \( A \), use the syntax:

\[
\text{static operator (x:B) as ?} \{ c \} = \ldots
\]

The \( ? \) indicates the containing type \( A \). The guard clause \( \{ c \} \) may be omitted.

**Example:**

```java
class Poly {
    public val coeff : Rail[Long];
    public def this(coeff: Rail[Long]) { this.coeff = coeff;}
    public static operator (a:Long) as ? = new Poly([a as Long]);
    public static def main(Rail[String]):void {
        val three : Poly = 3L as Poly;
    }
}
```

The \( ? \) may be given a bound, such as \( ? <: \text{ Caster} \), if desired.

There is little difference between an explicit conversion \( e \text{ as } T \) and a method call \( e.asT() \). The explicit conversion does say undeniably what the result type will be. However, as described in §11.22.3, sometimes the built-in meaning of \( as \) as a cast overrides the user-defined explicit conversion.

Explicit casts are most suitable for cases which resemble the use of explicit casts among the arithmetic types, where, for example, \( 1.0 \text{ as } \text{Int} \) is a way to turn a floating-point number into the corresponding integer. While there is nothing in X10 which requires it, \( e \text{ as } T \) has the connotation that it gives a good approximation of \( e \) in type \( T \), just as \( 1 \) is a good (indeed, perfect) approximation of \( 1.0 \) in type \( \text{Int} \).

8.7.4 Implicit Type Coercions

An implicit type conversion from \( U \) to \( T \) may be specified in container \( T \). The syntax for it is:

\[
\text{static operator (u:U) : } T = e;
\]

Implicit coercions are used automatically by the compiler on method calls (§8.12) and assignments (§11.7). Implicit coercions may be used when a value of type \( T \) appears in a context expecting a value of type \( U \). If \( T <: U \), no implicit coercion is needed; e.g., a method \( m \) expecting an \( \text{Long} \) argument may be called as \( m(3) \), with an argument of type \( \text{long} \{\text{self}==3\} \), which is a subtype of \( m \)'s argument type \( \text{Long} \). However, if it is not the case that \( T <: U \), but there is an implicit coercion from \( T \) to \( U \) defined in container \( U \), then this implicit coercion will be applied.
Example: We can define an implicit coercion from \texttt{Long} to \texttt{Poly}, and avoid having to define the sum of an integer and a polynomial as many special cases. In the following example, we only define $+$ on two polynomials. The calculation $1+x$ coerces 1 to a polynomial and uses polynomial addition to add it to $x$.

\begin{verbatim}
public static operator (c : Long) : Poly
    = new Poly([c as Long]);

public static operator (p:Poly) + (q:Poly) = new Poly(
    new Rail[Long](
        Math.max(p.coeff.size, q.coeff.size),
        (i:Long) => p.a(i) + q.a(i)
    ));

public static def main(Rail[String]):void {
    val x = new Poly([0L,1L]);
    x10.io.Console.OUT.println("1+x=" + (1L+x));
}
\end{verbatim}

8.7.5 Assignment and Application Operators

\textit{X10} allows types to implement the subscripting / function application operator, and indexed assignment. The Array-like classes take advantage of both of these in $a(i) = a(i) + 1$.

$a(b,c,d)$ is an operator call, to an operator defined with \texttt{public operator this(b:B, c:C, d:D)}. It may be overloaded. For example, an ordered dictionary structure could allow subscripting by numbers with \texttt{public operator this(i:Long)}, and by strings with \texttt{public operator this(s: String)}.

$a(i,j)=b$ is an operator as well, with zero or more indices $i,j$. It may also be overloaded.

The update operations $a(i) += b$ (for all binary operators in place of $+$) are defined to be the same as the corresponding $a(i) = a(i) + b$. This applies for all arities of arguments, and all types, and all binary operations. Of course to use this, the $+$, application and assignment operators must be defined.

Example:

\textit{The \texttt{Oddvec} class of somewhat peculiar vectors illustrates this.}

\texttt{a()} returns a string representation of the \texttt{oddvec}, which ordinarily would \textit{not} be done by \texttt{toString()} instead. \texttt{a(i)} sensibly picks out one of the three coordinates of \texttt{a}. \texttt{a()}=$b$ sets all the coordinates of \texttt{a} to \texttt{b}. \texttt{a(i)}=$b$ assigns to one of the coordinates. \texttt{a(i,j)}=$b$ assigns different values to \texttt{a(i)} and \texttt{a(j)}.

\begin{verbatim}
class Oddvec {
    var v : Rail[Long] = new Rail[Long](3);
}
\end{verbatim}
public operator this () =
"(" + v(0) + "," + v(1) + "," + v(2) + ")";
public operator this () = (newval: Long) {
    for(p in v.range) v(p) = newval;
}
public operator this(i:Long) = v(i);
public operator this(i:Long, j:Long) = [v(i),v(j)];
public operator this(i:Long) = (newval:Long)
    {v(i) = newval;}
public operator this(i:Long, j:Long) = (newval:Long)
    { v(i) = newval; v(j) = newval+1;}
public def example() {
    this(1) = 6; assert this(1) == 6;
    this(1) += 7; assert this(1) == 13;
}

### 8.8 User-Defined Control Structures

```
KeywordOpDecln ::= MethMods operator keywordOp TypeParams? Formals Guard? (20.105)
                     Throws? HasResultType? MethodBody

KeywordOp ::= for
             | if
             | try
             | throw
             | async
             | atomic
             | when
             | finish
             | at
             | continue
             | break
             | ateach
             | while
             | do
```

Similarly to user-defined operators (Section 8.7), it is possible to redefine the behavior of some control structures. For example, suppose that we want to define a if statement that randomly chooses which branch to execute. In a class RandomIf, we define a method named if (introduced with the keyword operator) that implements this behavior:

```java
class RandomIf {
    val random = new Random();
    public operator if(then: ()=>void, else_: ()=>void) {
```
8.8. USER-DEFINED CONTROL STRUCTURES

```java
if (random.nextBoolean()) {
    then();
} else {
    else_();
}
```

Then, we can call this method using the syntax of the if statement by prefixing the if keyword by an object that implements this method:

```java
val random = new RandomIf();
random.if () {
    Console.OUT.println("true");
} else {
    Console.OUT.println("false");
}
```

The blocks that represent the then and the else branches of the if are automatically turned into closures and are given as argument to the RandomIf.if method.

To distinguish the use of a user-defined control structure from the use of a built-in one, the first keyword of the control structure must be prefixed with the object that redefines its behavior. The scoping and dispatching rules of user-defined control structures are exactly the same as the rules for methods.

User-defined control structures can also be called as standard methods using the keyword operator as prefix (as for user-defined operators). For example, the previous code is equivalent to:

```java
val random = new RandomIf();
random.operator if (() => { Console.OUT.println("true"); }, () => { Console.OUT.println("false"); });
```

The correspondence between the two invocation syntaxes is formally specified in Figure 8.1 for all the control structures we support. It uses the following conventions: $o$ is either a class path or an object; $T$ is a list of types; $x:t$ is a list of variable declaration with their types; $\tau$ is a list of expressions; $b$ is a closure body: a list of statements between curly braces that can optionally end with an expression (a return value); $(\_)^?\equiv$ is an optional group.

Let’s consider the rule for if:

$$o.\text{if}[T]^{\tau}(\tau)\ b_1 (\text{else } b_2)^? \equiv o.\text{operator if}[T]^{\tau}(\tau, \_\Rightarrow b_1(_, \_\Rightarrow b_2)^?)$$

Compared to the builtin if control structure, the user-defined one accepts type arguments and replaces one condition expression with a list of expressions, possibly empty. The branches of the user-defined if statement are lifted to no-arg closures and passed to the user-defined if method as arguments. The else branch is optional.
The correspondence is purely syntactic. In other words, the control structure syntax is simply rewritten into the regular method invocation syntax with no consideration of types or method lookup.

### 8.8.1 User-Defined for

$$\text{o}.\text{for}[T]^\gamma(\tau, \text{in} \, (x:T \text{ in } c)) \equiv \text{o}.\text{operator for}[T]^\gamma(\tau, (x:T) \Rightarrow b)$$

A for loop over a collection may be defined in a container A as:

$$\text{operator for}[T](c: \text{Iterable}[T], \text{body: (T)=>void}) = \ldots$$

The use of such a user-defined for loop would have the following form:

$$A.\text{for} \ (x: T \text{ in } c) \ \{ \ldots \}$$

and would correspond to the following method call:

$$A.\text{operator for} \ (c, (x: \text{Long}) \Rightarrow \{ \ldots \});$$
The body of the `for` is automatically translated into a closure that takes the iteration variable as parameter. Since there is no type inference for closure parameters, the type of the iteration variable must be given explicitly.

The second argument of a `for` method can be a closure without argument:

```java
operator for[T](c: Iterable[T], body: ()=>void) = ...
```

In this case, the method is called using the syntax of a `for` loop without iteration variable:

```java
A.for (c) { ... }
```

**Example:** A naive implementation of a parallel loop can be:

```java
class Parallel {
    public static operator for[T](c: Iterable[T], body: (T)=>void) {
        finish {
            for(x in c) {
                async { body(x); }
            }
        }
    }

    public static def main(Rail[String]) {
        val cpt = new Cell[Long](0);
        Parallel.for(i:Long in 1..10) {
            atomic { cpt() = cpt() + i; }
        }
        Console.OUT.println(cpt());
    }
}
```

**Example:** We can also use the user-defined `for` loops to define iterations over a two dimensional space. Let us define a loop that creates an activity for each element of the first dimension.

```java
class Parallel2 {
    public static operator for (space: DenseIterationSpace_2,
                                body: (i:Long, j:Long)=void) {
        finish {
            for (i in space.min0 .. space.max0) {
                async for (j in space.min1 .. space.max1) {
                    body(i, j);
                }
            }
        }
    }
}
```
and it can be used as follows:

```java
Parallel2.for (i:Long, j:Long in 1..10 * 1..10) { ... }
```

The list of variables before the `in` keyword becomes the parameters of the closure whose body is the body of the loop.

### 8.8.2 User-Defined `if`

\[
or\{T\}(\alpha) ~ b_1 \text{ (else) } b_2 \equiv
or\{T\}(\alpha, () \Rightarrow b_1, () \Rightarrow b_2);
\]

When we use a user-defined `if` statement, the condition is evaluated before calling the `if` method, but the then and else branches are implicitly lifted to closures without argument.

Note that the condition of a user-defined `if` statement can take an arbitrary number of arguments. This is why we were able to define the `Random.if` that does not take a condition.

### 8.8.3 User-Defined `try`

\[
ort\{T\}(\alpha) =\{\beta, (x:t) \Rightarrow b_2, () \Rightarrow b_3\}
\]

When we use a user-defined `try` statement, the body of the `try` is lifted to a closure without argument and handler is lifted to a closure that has the parameter of the `catch` as parameter. The `finally` block is also lifted to a closure without argument.

**Example:** The user-defined `try` construct can be used to provide a control structure that automatically removes the nesting of `MultipleExceptions`:

```java
class Flatten {

    public static operator try(body:()=>void, 
        handler:(MultipleExceptions)=>void) {
        try { body(); }
        catch (me: MultipleExceptions) {
            val exns = new GrowableRail[CheckedThrowable]();
            flatten(me, exns);
            handler (new MultipleExceptions(exns));
        }
    }

    private static def flatten(me:MultipleExceptions, 
            acc:GrowableRail[CheckedThrowable]) {
        for (e in me.exceptions) {
```
8.8. USER-DEFINED CONTROL STRUCTURES

```java
if (e instanceof MultipleExceptions) {
    flatten(e as MultipleExceptions, acc);
} else {
    acc.add(e);
}
```

Used in the following example, the `MultipleExceptions` me contains the exceptions `Exception("Exn 1"), Exception("Exn 2"), and Exception("Exn 3") instead of the exception `Exception("Exn 1") and another `MultipleExceptions`.

```java
public static def main(Rail[String]) {
    Flatten.try {
        finish {
            async { throw new Exception("Exn 1"); }
            async finish {
                async { throw new Exception("Exn 2"); }
                async { throw new Exception("Exn 3"); }
            }
        }
    }
    catch (me: MultipleExceptions) {
        Console.OUT.println(me.exceptions);
    }
}
```

8.8.4 User-Defined `throw`

\[
o.\text{throw}[\mathcal{T}]^\circ\ e^\circ; \equiv o.\text{operator} \text{throw}[\mathcal{T}]^\circ(e^\circ);
\]

The argument of a user-defined `throw` is evaluated before calling the `throw` method.

8.8.5 User-Defined `async`

\[
o.\text{async}[\mathcal{T}]^\circ(\mathcal{e}_1)^\circ(\text{clocked} (\mathcal{e}_2))^\circ b \equiv o.\text{operator} \text{async}[\mathcal{T}]^\circ((\mathcal{e}_1),^\circ (\mathcal{e}_2),^\circ ()=> b);
\]

The body of a user-defined `async` is lifted to a closure without argument. The clock arguments are evaluated before the call to the `async` method.

**Example:** An `async` that does not execute in the scope in which it is written. The task is created in the scope where the object that defines the `async` method is instantiated.
class Escape {
    private var task: () => void = null;
    private var stop: Boolean = false;

    public def this() {
        async {
            while (!stop) {
                val t: () => void;
                when (task != null || stop) {
                    t = task;
                    task = null;
                }
                if (t != null) {
                    async { t(); }
                }
            }
        }
    }

    public operator async (body: () => void) {
        when (task == null) {
            task = body;
        }
    }

    public def stop() {
        atomic { stop = true; }
    }
}

In the following example, the message "OK" is printed even if the created task never terminates because the task is executed outside of the scope of the finish.

    public static def main(Rail[String]) {
        val toplevel = new Escape();
        finish {
            toplevel.async { when (false){} }
        }
        Console.OUT.println("OK");
    }

8.8.6 User-Defined atomic

\[ o.\text{atomic}(\overline{T})^\tau (r)^\gamma_b \equiv o.\text{operator atomic}(\overline{T})^\tau (r)^\gamma () => b; \]

The body of a user-defined atomic statement is lifted to a closure without argument.
8.8.7 User-Defined when
\[ o \cdot \text{when}[\overline{T}](\overline{\tau}) \ b \equiv o \cdot \text{operator when}[\overline{T}](\overline{\tau}, \_\Rightarrow b); \]

The arguments of a user-defined when statements are evaluated before the call of the when method and the body is lifted to a closure without argument. It means that if the argument of a user-defined when is of type Boolean, the condition is evaluated once and cannot be changed. To be able to update the condition, it can be an object with mutable field as in the following example or a closure.

Example: We can provide a when statement whose execution can be canceled while it is waiting:

```scala
class CancelableWhen {
  private var stop : Boolean = false;

  public operator when(condition:Cell[Boolean], body:()=>void) {
    when (condition() || stop) {
      if (!stop) { body(); }
    }
  }

  public def cancel() {
    atomic { stop = true; }
  }
}
```

The following example will not print the message "KO" but will terminate even if the condition b of the when remains false:

```scala
public static def main(Rail[String]) {
  val c = new CancelableWhen();
  val b = new Cell[Boolean](false);
  finish {
    async {
      c.when(b) { Console.OUT.println("KO"); }
    }
    c.cancel();
  }
}
```

8.8.8 User-Defined finish
\[ o \cdot \text{finish}[\overline{T}](\overline{\tau}) \ b \equiv o \cdot \text{operator finish}[\overline{T}](\overline{\tau}, \_\Rightarrow b); \]

The body of a user-defined finish is lifted to a closure.

Example: We define a finish that provide the ability to some parallel task to wait for its termination:
class SignalingFinish {
    private var terminated : Boolean = false;
    public operator finish(body: ()=>void) {
        finish {
            body();
        }
        atomic { terminated = true; }
    }
    public def join() {
        when (terminated) {}
    }
}

The following example will always print the message "before" before the message "after".

public static def main(Rail[String]) {
    val t = new SignalingFinish();
    async {
        t.join();
        Console.OUT.println("after");
    }
    t.finish {
        Console.OUT.println("before");
    }
}

8.8.9 User-Defined at

\[ o.\texttt{at}[\mathcal{T}](\tau) \ b \equiv o.\texttt{operator \ at}[\mathcal{T}](\tau, ()\Rightarrow b); \]

The arguments of the user-defined at statement are evaluated before the call of the at method and the body of the statement is lifted to a closure without argument.

Example: We define a class Ring implementing an at statement without argument. Each call to this user-defined at statement moves the activity to the next place in the place group given when the object is instantiated.

class Ring {
    val places: PlaceGroup;

    public def this (places: PlaceGroup) {
        this.places = places;
    }

    public operator at(body: ()\Rightarrow void) {

8.8. USER-DEFINED CONTROL STRUCTURES

```java
at(places.next(here)) { body(); }
}
public static def main(Rail[String]) {
    val r = new Ring(Place.places());
r.at() {
    Console.OUT.println("Hello from "+here+"!");
r.at() {
    Console.OUT.println("Hello from "+here+"!");
    }
}
}
```

8.8.10 User-Defined ateach

```java
o.ateach[T](\(x:T\) in \(\tau\)) b \equiv
o.operator ateach[T](\(\tau\), (\(x:T\)) => b);
```

The arguments of the user-defined ateach statement are evaluated before the call of the ateach method and the body of the statement is lifted to a closure without argument.

**Example:** An ateach control structure that has the same behavior as the built-in ateach, except that the activities are executed in sequence instead of being executed in parallel.

```java
class Sequential {
    public static operator ateach (d: Dist, body:(Point)=>void) {
for (place in d.places()) {
at(place) {
    for (p in d|here) { body(p); }
}
    }
}
}
```

8.8.11 User-Defined while and do

```java
o.while[T](\(\tau\)) b \equiv o.operator while[T](\(\tau\), () => b);
o.do[T] b while (\(\tau\)); \equiv o.operator do[T](() => b, \(\tau\));
```

The arguments of the user-defined while (resp. do) are evaluated before the call of the while (resp. do) method and the body of the loop is lifted to a closure without argument. Note that compared to usual loop, the condition is evaluated once before the call of the method that implements the behavior of the loop.

**Example:** A loop that iterates during at least a given number of milliseconds:
class Timeout {
    public static operator while(ms: Long, body: ()=>void) {
        val deadline = System.currentTimeMillis() + ms;
        while (System.currentTimeMillis() < deadline) {
            body();
        }
    }
}

Here, we increment a counter during a period of at least 10 milliseconds:

    public static def main(Rail[String]) {
        val cpt = new Cell[Long](0);
        Timeout.while(10) {
            atomic { cpt() = cpt() + 1; }
        }
        Console.OUT.println(cpt());
    }

8.8.12 User-Defined continue

    o.continue[T](e); ≡ o.operator continue[T](e);

The argument of a user-defined continue is evaluated before calling the corresponding method.

Example: The following code provides a parallel for loop with a continue statement that allows skipping an iteration.

    class Par {
        private static class Continue extends Exception {}

        public static operator continue () {
            throw new Continue();
        }

        public static operator for[T](c: Iterable[T], body:(T)=>void) {
            finish {
                for(x in c) async {
                    try {
                        body(x);
                    } catch (Continue) {}
                }
            }
        }
    }
The following example skips every iteration where the loop index is even.

```java
public static def main(Rail[String]) {
  val cpt = new Cell[Long](0);
  Par.for(i:Long in 1..10) {
    if (i%2 == 0) { Par.continue; }
    atomic { cpt() = cpt() + 1; }
  }
  Console.OUT.println(cpt());
}
```

### 8.8.13 User-Defined break

\[
o\text{.break}[\mathcal{T}] e^2; \quad \equiv \quad o\text{.operator break}[\mathcal{T}]^o(e^2);
\]

The argument of a user-defined break is evaluated before calling the corresponding method.

**Example:** To break out of a user-defined loop, it is necessary to also define the `break` statement:

```java
class Infinite {
  private static class Break extends Exception {}

  public static operator break () {
    throw new Break();
  }

  public static operator while (body:()=>void) {
    try {
      while(true) {
        body();
      }
    } catch (Break) {}
  }

  public static def main(Rail[String]) {
    Infinite.while() {
      Infinite.break();
    }
    Console.OUT.println("OK");
  }
}
```
8.9 Class Guards and Invariants

Classes (and structs and interfaces) may specify a class guard, a constraint which must hold on all values of the class. In the following example, a Line is defined by two distinct Pts:

```scala
class Pt(x:Long, y:Long){}
class Line(a:Pt, b:Pt){a != b} {}  
```

In most cases the class guard could be phrased as a type constraint on a property of the class instead, if preferred. Arguably, a symmetric constraint like two points being different is better expressed as a class guard, rather than asymmetrically as a constraint on one type:

```scala
class Line(a:Pt, b:Pt{a != b}) {}  
```

With every container or interface T we associate a type invariant inv(T), which describes the guarantees on the properties of values of type T.

Every value of T satisfies inv(T) at all times. This is somewhat stronger than the concept of type invariant in most languages (which only requires that the invariant holds when no method calls are active). X10 invariants only concern properties, which are immutable; thus, once established, they cannot be falsified.

The type invariant associated with x10.lang.Any is true.

The type invariant associated with any interface or struct I that extends interfaces I_1, ..., I_k and defines properties x_1: P_1, ..., x_n: P_n and specifies a guard c is given by:

\[
\text{inv}(I_1) \land ... \land \text{inv}(I_k) \land \text{self.x}_1 \text{ instanceof P}_1 \land ... \land \text{self.x}_n \text{ instanceof P}_n \land c
\]

Similarly the type invariant associated with any class C that implements interfaces I_1, ..., I_k, extends class D and defines properties x_1: P_1, ..., x_n: P_n and specifies a guard c is given by the same thing with the invariant of the superclass D conjoined:

\[
\text{inv}(I_1) \land ... \land \text{inv}(I_k) \land \text{self.x}_1 \text{ instanceof P}_1 \land ... \land \text{self.x}_n \text{ instanceof P}_n \land c \land \text{inv}(D)
\]

Note that the type invariant associated with a class entails the type invariants of each interface that it implements (directly or indirectly), and the type invariant of each ancestor class. It is guaranteed that for any variable v of type T{c} (where T is an interface name or a class name) the only objects o that may be stored in v are such that o satisfies \(\text{inv}(T[o/this]) \land c[o/self]\).

---

6We use Pt to avoid any possible confusion with the built-in class Point.
8.9. CLASS GUARDS AND INVARIANTS

8.9.1 Invariants for implements and extends clauses

Consider a class definition

```
ClassModifiers?
class C(x_1: P_1, ..., x_n: P_n){c} extends D{d}
  implements I_1{c_1}, ..., I_k{c_k}
ClassBody
```

These two rules must be satisfied:

- The type invariant \( inv(C) \) of \( C \) must entail \( c_i \{ \text{this/self} \} \) for each \( i \) in \( \{1, ..., k\} \)
- The return type \( c \) of each constructor in a class \( C \) must entail the invariant \( inv(C) \).

8.9.2 Timing of Invariant Checks

The invariants for a container are checked immediately after the property statement in the container’s constructor. This is the earliest that the invariant could possibly be checked. Recall that an invariant can mention the properties of the container (which are set, forever, at that point in the code), but cannot mention the \( \text{val} \) or \( \text{var} \) fields (which might not be set at that point), or \text{this} (which might not have been fully initialized).

If X10 can prove that the invariant always holds given the property statement and other known information, it may omit the actual check.

8.9.3 Invariants and constructor definitions

A constructor for a class \( C \) is guaranteed to return an object of the class on successful termination. This object must satisfy \( inv(C) \), the class invariant associated with \( C \). However, often the objects returned by a constructor may satisfy stronger properties than the class invariant. X10’s dependent type system permits these extra properties to be asserted with the constructor in the form of a constrained type (the “return type” of the constructor):

```
CtorDecln ::= Mods? def this TypeParams? Formals Guard? HasResultType? CtorBody
```

The parameter list for the constructor may specify a guard that is to be satisfied by the parameters to the list.

**Example:** Here is another example, constructed as a simplified version of X10.regionarray.Region. The mockUnion method has the type, though not the value, that a true union method would have.
class MyRegion(rank:Long) {
    static type MyRegion(n:Long)=MyRegion{rank==n};
    def this(r:Long):MyRegion(r) {
        property(r);
    }
    def this(diag:Rail[Long]):MyRegion(diag.size){
        property(diag.size);
    }
    def mockUnion(r:MyRegion(rank)):MyRegion(rank) = this;
    def example() {
        val R1 : MyRegion(3L) = new MyRegion([4,4,4 as Long]);
        val R2 : MyRegion(3L) = new MyRegion([5,4,1]);
        val R3 = R1.mockUnion(R2); // inferred type MyRegion(3)
    }
}

The first constructor returns the empty region of rank r. The second constructor takes a Rail[Long] of arbitrary length n and returns a MyRegion(n) (intended to represent the set of points in the rectangular parallelopiped between the origin and the diag.)

The code in example typechecks, and R3's type is inferred as MyRegion(3).

Let C be a class with properties p_1: P_1, ..., p_n: P_n, and invariant c extending the constrained type D{d} (where D is the name of a class).

For every constructor in C the compiler checks that the call to super invokes a constructor for D whose return type is strong enough to entail d. Specifically, if the call to super is of the form super(e_1, ..., e_k) and the static type of each expression e_i is S_i, and the invocation is statically resolved to a constructor def this(x_1: T_1, ..., x_k: T_k){c}: D{d} then it must be the case that

- x_1: S_1, ..., x_i: S_i entails x_i: T_i (for i ∈ {1, ..., k})
- x_1: S_1, ..., x_k: S_k entails c
- d[a/self], x_1: S_1, ..., x_k: S_k entails d[a/self]

where a is a constant that does not appear in x_1: S_1 ∧ ... ∧ x_k: S_k.

The compiler checks that every constructor for C ensures that the properties p_1, ..., p_n are initialized with values which satisfy inv(T), and its own return type c' as follows. In each constructor, the compiler checks that the static types T_i of the expressions e_i assigned to p_i are such that the following is true:

- p_1: T_1, ..., p_n: T_n entails inv(T) ∧ c'

(Note that for the assignment of e_i to p_i to be type-correct it must be the case that p_i: T_i ∧ p_i: P_i)

The compiler must check that every invocation C(e_1, ..., e_n) to a constructor is type correct: each argument e_i must have a static type that is a subtype of the declared type T_i for the i_th argument of the constructor, and the conjunction of static types of the argument must entail the constraint in the parameter list of the constructor.
8.10 Generic Classes

Classes, like other units, can be generic. They can be parameterized by types. The parameter types are used just like ordinary types inside the body of the generic class – with a few exceptions.

Example: A Colorized[T] holds a thing of type T, and a string which is intended to represent its color. Any type can be used for T; the example method shows Long and Boolean. The thing() method retrieves the thing; note that its return type is the generic type variable T. X10 is aware that colLong.thing() is an Long and colTrue.thing() is a Boolean, and uses those typings in example.

```scala
class Colorized[T] {
  private var thing:T;
  private var color:String;
  def this(thing:T, color:String) {
    this.thing = thing;
    this.color = color;
  }
  public def thing():T = thing;
  public def color():String = color;
  public static def example() {
    val colLong : Colorized[Long] = new Colorized[Long](3, "green");
    assert colLong.thing() == 3
    && colLong.color().equals("green");
    val colTrue : Colorized[Boolean] = new Colorized[Boolean](true, "blue");
    assert colTrue.thing()
    && colTrue.color().equals("blue");
  }
}
```

8.10.1 Use of Generics

An unconstrained type variable X can be instantiated by any type. All the operations of Any are available on a variable of type X. Additionally, variables of type X may be used with ==, !=, in instanceof, and casts.

If a type variable is constrained, the operations implied by its constraint are available as well.

Example: The interface Named describes entities which know their own name. The class NameMap[T] is a specialized map which stores and retrieves Named entities by name. The call t.name() in put() is only valid because the constraint {T <: Named} implies that T is a subtype of Named, and hence provides all the operations of Named.
interface Named { def name():String; }
class NameMap[T]{T <: Named, T haszero} {
  val m = new HashMap[String, T]();
  def put(t:T) { m.put(t.name(), t); } 
  def get(s:String):T = m.getOrElse(s);
}

8.11 Object Initialization

X10 does object initialization safely. It avoids certain bad things which trouble some other languages:

1. Use of a field before the field has been initialized.
2. A program reading two different values from a val field of a container.
3. this escaping from a constructor, which can cause problems as noted below.

It should be unsurprising that fields must not be used before they are initialized. At best, it is uncertain what value will be in them, as in x below. Worse, the value might not even be an allowable value; y, declared to be nonzero in the following example, might be zero before it is initialized.

// Not correct X10
class ThisIsWrong {
  val x : Long;
  val y : Long{y != 0};
  def this() {
    x10.io.Console.OUT.println("x=" + x + "; y=" + y);
    x = 1; y = 2;
  }
}

One particularly insidious way to read uninitialized fields is to allow this to escape from a constructor. For example, the constructor could put this into a data structure before initializing it, and another activity could read it from the data structure and look at its fields:

class Wrong {
  val shouldBe8 : Long;
  static Cell[Wrong] wrongCell = new Cell[Wrong]();
  static def doItWrong() {
    finish {
      async { new Wrong(); } // (A)
      assert( wrongCell().shouldBe8 == 8); // (B)
    }
  }
}
8.11. OBJECT INITIALIZATION

```scala
}
def this() {
    wrongCell.set(this); // (C) - ILLEGAL
    this.shouldBe8 = 8; // (D)
}
```

In this example, the underconstructed `Wrong` object is leaked into a storage cell at line (C), and then initialized. The `doItWrong` method constructs a new `Wrong` object, and looks at the `Wrong` object in the storage cell to check on its `shouldBe8` field. One possible order of events is the following:

1. `doItWrong()` is called.

2. (A) is started. Space for a new `Wrong` object is allocated. Its `shouldBe8` field, not yet initialized, contains some garbage value.

3. (C) is executed, as part of the process of constructing a new `Wrong` object. The new, uninitialized object is stored in `wrongCell`.

4. Now, the initialization activity is paused, and execution of the main activity proceeds from (B).

5. The value in `wrongCell` is retrieved, and is `shouldBe8` field is read. This field contains garbage, and the assertion fails.

6. Now let the initialization activity proceed with (D), initializing `shouldBe8` — too late.

The `at` statement (§13.3) introduces the potential for escape as well. The following class prints an uninitialized value:

```scala
// This code violates this chapter's constraints
// and thus will not compile in X10.
class Example {
    val a: Long;
    def this() {
        at(here.next()) {
            // Recall that 'this' is a copy of 'this' outside 'at'.
            Console.OUT.println("this.a = " + this.a);
        }
        this.a = 1;
    }
}
```

X10 must protect against such possibilities. The rules explaining how constructors can be written are somewhat intricate; they are designed to allow as much programming as possible without leading to potential problems. Ultimately, they simply are elaborations of the fundamental principles that uninitialized fields must never be read, and `this` must never be leaked.
8.11.1 Constructors and Non-Escaping Methods

In general, constructors must not be allowed to call methods with `this` as an argument or receiver. Such calls could leak references to `this`, either directly from a call to `cell.set(this)`, or indirectly because `toString` leaks this, and the concatenation

"Escaper = " + this"

// This code violates this chapter's constraints
// and thus will not compile in X10.
class Escaper {
    static val Cell[Escaper] cell = new Cell[Escaper]();
    def toString() {
        cell.set(this);
        return "Evil!";
    }
    def this() {
        cell.set(this);
        x10.io.Console.OUT.println("Escaper = " + this);
    }
}

However, it is convenient to be able to call methods from constructors; e.g., a class might have eleven constructors whose common behavior is best described by three methods. Under certain stringent conditions, it is safe to call a method: the method called must not leak references to `this`, and must not read vals or vars which might not have been assigned.

So, X10 performs a static dataflow analysis, sufficient to guarantee that method calls in constructors are safe. This analysis requires having access to or guarantees about all the code that could possibly be called. This can be accomplished in two ways:

1. Ensuring that only code from the class itself can be called, by forbidding over-riding of methods called from the constructor: they can be marked `final` or `private`, or the whole class can be `final`.

2. Marking the methods called from the constructor by `@NonEscaping` or `@NoThisAccess`.

Non-Escaping Methods

A method may be annotated with `@NonEscaping`. This imposes several restrictions on the method body, and on all methods overriding it. However, it is the only way that a method can be called from constructors. The `@NonEscaping` annotation makes explicit all the X10 compiler's needs for constructor-safety.

A method can, however, be safe to call from constructors without being marked `@NonEscaping`. We call such methods *implicitly non-escaping*. Implicitly non-escaping methods need

---

7This is abominable behavior for `toString`, but it cannot be prevented – save by a scheme such as we present in this section.
8.11. **OBJECT INITIALIZATION**

To obey the same constraints on `this`, `super`, and variable usage as `@NonEscaping` methods. An implicitly non-escaping method *could* be marked as `@NonEscaping`; the compiler, in effect, infers the annotation. In addition, all non-escaping methods must be private or final or members of a final class; this corresponds to the hereditary nature of `@NonEscaping` (by forbidding inheritance of implicitly non-escaping methods).

We say that a method is *non-escaping* if it is either implicitly non-escaping, or annotated `@NonEscaping`.

The first requirement on non-escaping methods is that they do not allow `this` to escape. Inside of their bodies, `this` and `super` may only be used for field access and assignment, and as the receiver of non-escaping methods.

The following example uses the possible variations. `aplomb()` explicitly forbids reading any field but `a`. `boric()` is called after `a` and `b` are set, but `c` is not. The `@NonEscaping` annotation on `boric()` is optional, but the compiler will print a warning if it is left out. `cajoled()` is only called after all fields are set, so it can read anything; its annotation, too, is not required. SeeAlso is able to override `aplomb()`, because `aplomb()` is `@NonEscaping`; it cannot override the final method `boric()` or the private one `cajoled()`.

```scala
import x10.compiler.*;

final class C2 {
  protected val a:Long; protected val b:Long; protected val c:Long;
  protected var x:Long; protected var y:Long; protected var z:Long;
  def this() {
    a = 1;
    this.aplomb();
    b = 2;
    this.boric();
    c = 3;
    this.cajoled();
  }

  @NonEscaping def aplomb() {
    x = a;
    // this.boric(); // not allowed; boric reads b.
    // z = b; // not allowed -- only 'a' can be read here
  }

  @NonEscaping final def boric() {
    y = b;
    this.aplomb(); // allowed;
    // a is definitely set before boric is called
    // z = c; // not allowed; c is not definitely written
  }

  @NonEscaping private def cajoled() {
    z = c;
  }
}
```
NoThisAccess Methods

A method may be annotated @NoThisAccess. @NoThisAccess methods may be called from constructors, and they may be overridden in subclasses. However, they may not refer to this in any way – in particular, they cannot refer to fields of this, nor to super.

Example:

The class IDed has an Float-valued id field. The method count() is used to initialize the id. For IDed objects, the id is the count of IDeds created with the same parity of its kind. Note that count() does not refer to this, though it does refer to a static field counts.

The subclass SubIDed has ids that depend on kind%3 as well as the parity of kind. It overrides the count() method. The body of count() still cannot refer to this. Nor can it refer to super (which is self under another name). This precludes the use of a super call. This is why we have separated the body of count out as the static method kind2count – without that, we would have had to duplicate its body, as we could not call super.count(kind) in a NoThisAccess method, as is shown by the ERROR line (A).

Note that NoThisAccess is in x10.compiler and must be imported, and that the overriding method SubIDed.count must be declared @NoThisAccess as well as the overridden method. Line (B) is not allowed because code is a field of this, and field accesses are forbidden. Line (C) references this directly, which, of course, is forbidden by @NoThisAccess.

```java
import x10.compiler.*;
class UseNoThisAccess {
    static class IDed {
        protected static val counts = [0 as Long, 0];
        protected var code : Long;
        val id: Float;
        public def this(kind:Long) {
            code = kind;
            this.id = this.count(kind);
        }
        protected static def kind2count(kind:Long) = ++counts(kind % 2);
        @NoThisAccess def count(kind:Long) : Float = kind2count(kind);
    }
    static class SubIDed extends IDed {
        protected static val subcounts = [0 as Long, 0, 0];
        public static val all = new x10.util.ArrayList[SubIDed]();
        public def this(kind:Long) {
```
8.11. OBJECT INITIALIZATION

8.11.2 Fine Structure of Constructors

The code of a constructor consists of four segments, three of them optional and one of them implicit.

1. The first segment is an optional call to this(...) or super(...). If this is supplied, it must be the first statement of the constructor. If it is not supplied, the compiler treats it as a nullary super-call super();

2. If the class or struct has properties, there must be a single property(...) command in the constructor, or a this(...) constructor call. Every execution path through the constructor must go through this property(...) command precisely once. The second segment of the constructor is the code following the first segment, up to and including the property() statement.

   If the class or struct has no properties, the property() call must be omitted. If it is present, the second segment is defined as before. If it is absent, the second segment is empty.

3. The third segment is automatically generated. Fields with initializers are initialized immediately after the property statement. In the following example, \( b \) is initialized to \( y^9000 \) in segment three. The initialization makes sense and does the right thing: \( b \) will be \( y^9000 \) for every Overdone object. (This would not be possible if field initializers were processed earlier, before properties were set.)

4. The fourth segment is the remainder of the constructor body.

The segments in the following code are shown in the comments.

```scala
class Overlord(x:Long) {
  def this(x:Long) { property(x); }
}//Overlord
class Overdone(y:Long) extends Overlord {
  super(kind);
}
@NoThisAccess
def count(kind:Long) : Float {
  val subcount <: Long = ++subcounts(kind % 3);
  val supercount <: Float = kind2count(kind);
  return supercount + 1.0f / subcount;
}
```
val a : Long;
val b = y * 9000;
def this(r:Long) {
    super(r); // (1)
x10.io.Console.OUT.println(r); // (2)
    val rp1 = r+1;
    property(rp1);
    // field initializations here // (3)
    a = r + 2 + b; // (4)
}
def this() {
    this(10); // (1), (2), (3)
    val x = a + b; // (4)
}
} // Overdone

The rules of what is allowed in the three segments are different, though unsurprising.
For example, properties of the current class can only be read in segment 3 or 4—naturally, because they are set at the end of segment 2.

Initialization and Inner Classes

Constructors of inner classes are tantamount to method calls on this. For example, the constructor for Inner is acceptable. It does not leak this. It leaks Outer.this, which is an utterly different object. So, the call to this.new Inner() in the Outer constructor is illegal. It would leak this. There is no special rule in effect preventing this; a constructor call of an inner class is no different from a method as far as leaking is concerned.

class Outer {
    static val leak : Cell[Outer] = new Cell[Outer](null);
class Inner {
    def this() {Outer.leak.set(Outer.this);}
}
def /*Outer*/this() {
    //ERROR: val inner = this.new Inner();
}
}

Initialization and Closures

Closures in constructors may not refer to this. They may not even refer to fields of this that have been initialized. For example, the closure bad1 is not allowed because it refers to this; bad2 is not allowed because it mentions a — which is, of course, identical to this.a.
8.11. OBJECT INITIALIZATION

```java
class C {
    val a:Long;
    def this() {
        this.a = 1;
        //ERROR: val bad1 = () => this;
        //ERROR: val bad2 = () => a*10;
    }
}
```

8.11.3 Definite Initialization in Constructors

An instance field `var x:T`, when `T` has a default value, need not be explicitly initialized. In this case, `x` will be initialized to the default value of type `T`. For example, a `Score` object will have its `currently` field initialized to zero, below:

```java
class Score {
    public var currently : Long;
}
```

All other sorts of instance fields do need to be initialized before they can be used. `val` fields must be initialized in the constructor, even if their type has a default value. It would be silly to have a field `val z : Long` that was always given default value of `0` and, since it is `val`, can never be changed. `var` fields whose type has no default value must be initialized as well, such as `var y : Long{y != 0}`, since it cannot be assigned a sensible initial value.

The fundamental principles are:

1. `val` fields must be assigned precisely once in each constructor on every possible execution path.
2. `var` fields of defaultless type must be assigned at least once on every possible execution path, but may be assigned more than once.
3. No variable may be read before it is guaranteed to have been assigned.
4. Initialization may be by field initialization expressions (`val x : Long = y+z`), or by uninitialized fields `val x : Long` plus an initializing assignment `x = y+z`. Recall that field initialization expressions are performed after the `property` statement, in segment 3 in the terminology of §8.11.2.

8.11.4 Summary of Restrictions on Classes and Constructors

The following table tells whether a given feature is (yes), is not (no) or is with some conditions (note) allowed in a given context. For example, a property method is allowed
with the type of another property, as long as it only mentions the preceding properties. The first column of the table gives examples, by line of the following code body.

<table>
<thead>
<tr>
<th>Type of property</th>

</tbody>
</table>

Details:

- (1) Top-level self only.
- (2) The type of the $i^{th}$ property may only mention properties 1 through $i$.
- (3) Super-interfaces follow the same rules as supertypes.
- (4) The same rules apply to types and initializers.

The example indices refer to the following code:

```java
class Example {
    prop : Long,
    proq : Long{prop != proq}, // (A)
    pror : Long
}
{prop != 0} // (B)
extends Supertype[Long{self != prop}] // (C)
implements SuperInterface[Long{self != prop}] // (D)
{
    property def propmeth() = (prop == pror); // (E)
    static staticField
        : Cell[Long{self != 0}] // (F)
        = new Cell[Long{self != 0}](1); // (G)
    var instanceField
        : Long{self != prop} // (H)
        = (prop + 1) as Long{self != prop}; // (I)
def this(
    a : Long{a != 0},
```
8.12. METHOD RESOLUTION

Method resolution is the problem of determining, statically, which method (or constructor or operator) should be invoked, when there are several choices that could be invoked. For example, the following class has two overloaded zap methods, one taking an Any, and the other a Resolve. Method resolution will figure out that the call zap(1..4) should call zap(Any), and zap(new Resolve()) should call zap(Resolve).

Example:

class Res {
    public static interface Surface {}
    public static interface Deface {}

    public static class Ace implements Surface {
        public static operator (Boolean) : Ace = new Ace();
        public static operator (Place) : Ace = new Ace();
    }
    public static class Face implements Surface, Deface{}

    public static class A {}
    public static class B extends A {}
    public static class C extends B {}

    def m(x:A) = 0;
    def m(x:Long) = 1;
    def m(x:Boolean) = 2;
    def m(x:Surface) = 3;
    def m(x:Deface) = 4;
}

8.12 Method Resolution

b : Long{b != a}       // (J)
)                     
{a != b}             // (K)
: Example{self.prop == a && self.proq==b} // (L)

}  
super();               // (M)
property(a,b,a);       // (N)
// fields initialized here
instanceField = b as Long{self != prop};   // (O)

def someMethod() =
    prop + staticField() + instanceField;   // (P)
def example() {
    assert m(100) == 1 : "Long";
    assert m(new C()) == 0 : "C";
    // An Ace is a Surface, unambiguous best choice
    assert m(new Ace()) == 3 : "Ace";
    // ERROR: m(new Face());
    // The match must be exact.
    // ERROR: assert m(here) == 3 : "Place";
    // Boolean could be handled directly, or by
    // implicit coercion Boolean -> Ace.
    // Direct matches always win.
    assert m(true) == 2 : "Boolean";
}

In the "Long" line, there is a very close match. 100 is an Long. In fact, 100 is an Long{self=100}, so even in this case the type of the actual parameter is not precisely equal to the type of the method.

In the "C" line of the example, new C() is an instance of C, which is a subtype of A, so the A method applies. No other method does, and so the A method will be invoked.

Similarly, in the "Ace" line, the Ace class implements Surface, and so new Ace() matches the Surface method.

However, a Face is both a Surface and a Deface, so there is no unique best match for the invocation m(new Face()). This invocation would be forbidden, and a compile-time error issued.

The match must be exact. There is an implicit coercion from Place to Ace, and Ace implements Surface, so the code

    val ace : Ace = here;
    assert m(ace) == 3;

works, by using the Surface form of m. But doing it in one step requires a deeper search than X10 performs, and is not allowed.

For m(true), both the Boolean and, with the implicit coercion, Ace methods could apply. Since the Boolean method applies directly, and the Ace method requires an implicit coercion, this call resolves to the Boolean method, without an error.

The basic concept of method resolution is:

1. List all the methods that could possibly be used, inferring generic types but not performing implicit coercions.

2. If one possible method is more specific than all the others, that one is the desired method.

\[8\]In general this search is unbounded, so X10 can’t perform it.
3. If there are two or more methods neither of which is more specific than the others, then the method invocation is ambiguous. Method resolution fails and reports an error.

4. Otherwise, no possible methods were found without implicit coercions. Try the preceding steps again, but with coercions allowed: zero or one implicit coercion for each argument. If a single most specific method is found with coercions, it is the desired method. If there are several, the invocation is ambiguous and erronious.

5. If no methods were found even with coercions, then the method invocation is undetermined. Method resolution fails and reports an error.

After method resolution is done, there is a validation phase that checks the legality of the call, based on the STATIC_CHECKS compiler flag. With STATIC_CHECKS, the method’s constraints must be satisfied; that is, they must be entailed (§4.5.2) by the information in force at the point of the call. With DYNAMIC_CHECKS, if the constraint is not entailed at that point, a dynamic check is inserted to make sure that it is true at runtime.

In the presence of X10’s highly-detailed type system, some subtleties arise. One point, at least, is not subtle. The same procedure is used, mutatis mutandis for method, constructor, and operator resolution.

### 8.12.1 Space of Methods

X10 allows some constructs, particularly operators, to be defined in a number of ways, and invoked in a number of ways. This section specifies which forms of definition could correspond to a given definiendum.

Method invocations \( a.m(b) \), where \( a \) is an expression, can be either of the following forms. There may be any number of arguments.

- An instance method on \( a \), of the form \( \text{def } m(B) \).
- A static method on \( a \)'s class, of the form \( \text{static def } m(B) \).

The meaning of an invocation of the form \( m(b) \), with any number of arguments, depends slightly on its context. Inside of a constraint, it might mean \( \text{self.m(b)} \). Outside of a constraint, there is no \texttt{self} defined, so it can’t mean that. The first of these that applies will be chosen.

1. Invoke a method on \texttt{this}, \( \text{viz. this.m(b)} \). Inside a constraint, it may also invoke a property method on \texttt{self}, \( \text{viz. self.m(b)} \). It is an error if both \( \text{this.m(b)} \) and \( \text{self.m(b)} \) are possible.

2. Invoke a function named \( m \) in a local or field.
3. Construct a structure named \( m \).

Static method invocations, \( A.m(b) \), where \( A \) is a container name, can only be static. There may be any number of arguments.

- A static method on \( A \), of the form \( \text{static def } m(B) \).

Constructor invocations, \( \text{new } A(b) \), must invoke constructors. There may be any number of arguments.

- A constructor on \( A \), of the form \( \text{def this}(B) \).

A unary operator \( \star a \) may be defined as:

- An instance operator on \( A \), defined as \( \text{operator } \star \text{this}() \).
- A static operator on \( A \), defined as \( \text{operator } \star(a:A) \).

A binary operator \( a \star b \) may be defined as:

- An instance operator on \( A \), defined as \( \text{operator this } \star(b:B) \); or
- A right-hand operator on \( B \), defined as \( \text{operator } (a:A) \star \text{this}; \) or
- A static operator on \( A \), defined as \( \text{operator } (a:A) \star(b:B); \) or
- A static operator on \( B \), if \( A \) and \( B \) are different classes, defined as \( \text{operator } (a:A) \star(b:B) \).

If none of those resolve to a method, then either operand may be implicitly coerced to the other. If one of the following two situations obtains, it will be done; if both, the expression causes a static error.

- An implicit coercion from \( A \) to \( B \), and an operator \( \star B \) can be used, by coercing \( a \) to be of type \( B \), and then using \( B \)'s \( \star \).
- An implicit coercion from \( B \) to \( A \), and an operator \( \star A \) can be used, coercing \( b \) to be of type \( A \), and then using \( A \)'s \( \star \).

An application \( a(b) \), for any number of arguments, can come from a number of things.

- an application operator on \( a \), defined as \( \text{operator this}(b:B) \);
- If \( a \) is an identifier, \( a(b) \) can also be a method invocation equivalent to \( \text{this.}a(b) \), which invokes \( a \) as either an instance or static method on \( \text{this} \);
- If \( a \) is a qualified identifier, \( a(b) \) can also be an invocation of a struct constructor.
An indexed assignment, \(a(b) = c\), for any number of \(b\)'s, can only come from an indexed assignment definition:

- \texttt{operator this}(b:B) = (c:C) \{ ... \}

An implicit coercion, in which a value \(a:A\) is used in a context which requires a value of some other non-subtype \(B\), can only come from implicit coercion operation defined on \(B\):

- an implicit coercion in \(B\): \texttt{static operator} (a:A):B;

An explicit conversion \(a \text{ as } B\) can come from an explicit conversion operator, or an implicit coercion operator. X10 tries two things, in order, only checking 2 if 1 fails:

1. An as operator in \(B\): \texttt{static operator} (a:A) as ?;
2. or, failing that, an implicit coercion in \(B\): \texttt{static operator} (a:A):B.

### 8.12.2 Possible Methods

This section describes what it means for a method to be a possible resolution of a method invocation.

Generics introduce several subtleties, especially with the inference of generic types. For the purposes of method resolution, all that matters about a method, constructor, or operator \(M\) — we use the word “method” to include all three choices for this section — is its signature, plus which method it is. So, a typical \(M\) might look like \texttt{def} \(m[G_1, \ldots, G_g](x_1:T_1, \ldots, x_f:T_f)\{c\} = \ldots\). The code body \(\ldots\) is irrelevant for the purpose of whether a given method call means \(M\) or not, so we ignore it for this section.

All that matters about a method definition, for the purposes of method resolution, is:

1. The method name \(m\);
2. The generic type parameters of the method \(m\), \(G_1, \ldots, G_g\). If there are no generic type parameters, \(g = 0\).
3. The types \(x_1:T_1, \ldots, x_f:T_f\) of the formal parameters. If there are no formal parameters, \(f = 0\). In the case of an instance method, the receiver will be the first formal parameter\(^9\).
4. A unique identifier \(id\), sufficient to tell the compiler which method body is intended. A file name and position in that file would suffice. The details of the identifier are not relevant.

\(^9\)The variable names are relevant because one formal can be mentioned in a later type, or even a constraint: \texttt{def f(a:Long, b:Point{rank==a})=\ldots}. 
For the purposes of understanding method resolution, we assume that all the actual parameters of an invocation are simply variables: `x1.meth(x2, x3)`. This is done routinely by the compiler in any case; the code `tbl(i).meth(true, a+1)` would be treated roughly as

```ml
val x1 = tbl(i);
val x2 = true;
val x3 = a+1;
val x1.meth(x2, x3);
```

All that matters about an invocation `I` is:

1. The method name `m';`
2. The generic type parameters `G'_1, ..., G'_g`. If there are no generic type parameters, `g = 0`.
3. The names and types `x_1:T'_1, ..., x_f:T'_f` of the actual parameters. If there are no actual parameters, `f = 0`. In the case of an instance method, the receiver is the first actual parameter.

The signature of the method resolution procedure is: `resolve(invo : Invocation, context: Set[Method]) : MethodID`. Given a particular invocation and the set `context` of all methods which could be called at that point of code, method resolution either returns the unique identifier of the method that should be called, or (conceptually) throws an exception if the call cannot be resolved.

The procedure for computing `resolve(invo, context)` is:

1. Eliminate from `context` those methods which are not `acceptable`; viz., those whose name, type parameters, and formal parameters do not suitably match `invo`. In more detail:
   - The method name `m` must simply equal the invocation name `m';`
   - `X10` infers type parameters, by an algorithm given in §4.12.3
   - The method’s type parameters are bound to the invocation’s for the remainder of the acceptability test.
   - The actual parameter types must be subtypes of the formal parameter types, or be coercible to such subtypes. Parameter `i` is a subtype if `T'_i <: T_i`. It is implicitly coercible to a subtype if either it is a subtype, or if there is an implicit coercion operator defined from `T'_i` to some type `U`, and `U <: T_i`.
   - If coercions are used to resolve the method, they will be called on the arguments before the method is invoked.

2. Eliminate from `context` those methods which are not `available`; viz., those which cannot be called due to visibility constraints, such as methods from other classes marked private. The remaining methods are both acceptable and available; they might be the one that is intended.
3. If the method invocation is a super invocation appearing in class C1, methods of C1 and its subclasses are considered unavailable as well.

4. From the remaining methods, find the unique ms which is more specific than all the others, viz., for which specific(ms, mo) = true for all other methods mo. The specificity test specific is given next.

- If there is a unique such ms, then resolve(invo, context) returns the id of ms.
- If there is not a unique such ms, then resolve reports an error.

The subsidiary procedure specific(m1, m2) determines whether method m1 is equally or more specific than m2. specific is not a total order: is is possible for each one to be considered more specific than the other, or either to be more specific. specific is computed as:

1. Construct an invocation invo1 based on m1:
   - invo1’s method name is m1’s method name;
   - invo1’s generic parameters are those of m1— simply some type variables.
   - invo1’s parameters are those of m1.

2. If m2 is acceptable for the invocation invo1, specific(m1, m2) returns true;

3. Construct an invocation invo2p, which is invo1 with the generic parameters erased. Let invo2 be invo2p with generic parameters as inferred by X10’s type inference algorithm. If type inference fails, specific(m1, m2) returns false.

4. If m2 is acceptable for the invocation invo2, specific(m1, m2) returns true;

5. Otherwise, specific(m1, m2) returns false.

### 8.12.3 Field Resolution

An identifier p can refer to a number of things. The rules are somewhat different inside and outside of a constraint.

Outside of a constraint, the compiler chooses the first one from the following list which applies:

1. A local variable named p.
2. A field of this, viz. this.p.
3. A nullary property method, this.p().
4. A member type named p.

Inside of a constraint, the rules are slightly different, because self is available, and packages cannot be used per se.

1. A local variable named p.

2. A property of this or of self, viz. this.p or self.p. If both are available, report an error.

3. A nullary property method, this.p()

4. A member type named p.

### 8.12.4 Other Disambiguations

It is possible to have a field of the same name as a method. Indeed, it is a common pattern to have private field and a public method of the same name to access it: **Example:**

```scala
class Xhaver {
  private var x: Long = 0;
  public def x() = x;
  public def bumpX() { x ++; }
}
```

**Example:** However, this can lead to syntactic ambiguity in the case where the field f of object a is a function, rail, array, list, or the like, and where a has a method also named f. The term a.f(b) could either mean “call method f of a upon b”, or “apply the function a.f to argument b”.

```scala
class Ambig {
  public val f : (Long)=>Long = (x:Long) => x*x;
  public def f(y:int) = y+1;
  public def example() {
    val v = this.f(10);
    // is v 100, or 11?
  }
}
```

In the case where a syntactic form E.m(F₁, ..., Fₙ) could be resolved as either a method call, or the application of a field E.m to some arguments, it will be treated as a method call. The application of E.m to some arguments can be specified by adding parentheses: (E.m)(F₁, ..., Fₙ).

**Example:**
8.13. *STATIC NESTED CLASSES*

```scala
class Disambig {
  public val f : (Long)=>Long = (x:Long) => x*x;
  public def f(y:int) = y+1;
  public def example() {
    assert( this.f(10) == 11 );
    assert( (this.f)(10) == 100 );
  }
}
```

Similarly, it is possible to have a method with the same name as a struct, say `ambig`, giving an ambiguity as to whether `ambig()` is a struct constructor invocation or a method invocation. This ambiguity is resolved by treating it as a method invocation. If the constructor invocation is desired, it can be achieved by including the optional `new`. That is, `new ambig()` is struct constructor invocation; `ambig()` is a method invocation.

8.13 Static Nested Classes

One class (or struct or interface) may be nested within another. The simplest way to do this is as a static nested class, written by putting one class definition at top level inside another, with the inner one having a `static` modifier. For most purposes, a static nested class behaves like a top-level class. However, a static nested class has access to private static fields and methods of its containing class.

Nested interfaces and static structs are permitted as well.

```scala
class Outer {
  private static val priv = 1;
  private static def special(n:Long) = n*n;
  public static class StaticNested {
    static def reveal(n:Long) = special(n) + priv;
  }
}
```

8.14 Inner Classes

Non-static nested classes are called *inner classes*. An inner class instance can be thought of as a very elaborate member of an object — one with a full class structure of its own. The crucial characteristic of an inner class instance is that it has an implicit reference to an instance of its containing class.

**Example:** This feature is particularly useful when an instance of the inner class makes no sense without reference to an instance of the outer, and is closely tied to it. For example, consider a range class, describing a span of integers from `m` to `n`, and an
iterator over the range. The iterator might as well have access to the range object, and there is little point to discussing iterators-over-ranges without discussing ranges as well. In the following example, the inner class `RangeIter` iterates over the enclosing `Range`.

It has its own private cursor field `n`, telling where it is in the iteration; different iterations over the same `Range` can exist, and will each have their own cursor. It is perhaps unwise to use the name `n` for a field of the inner class, since it is also a field of the outer class, but it is legal. (It can happen by accident as well – e.g., if a programmer were to add a field `n` to a superclass of the outer class, the inner class would still work.) It does not even interfere with the inner class’s ability to refer to the outer class’s `n` field: the cursor initialization refers to the `Range`’s lower bound through a fully qualified name `Range.this.n`. The initialization of its `n` field refers to the outer class’s `m` field, which is not shadowed and can be referred to directly, as `m`.

```scala
class Range(m:Long, n:Long) implements Iterable[Long]{
  public def iterator () = new RangeIter();
  private class RangeIter implements Iterator[Long] {
    private var n : Long = m;
    public def hasNext() = n <= Range.this.n;
    public def next() = n++;
  }
  public static def main(argv:Rail[String]) {
    val r = new Range(3,5);
    for(i in r) Console.OUT.println("i=" + i);
  }
}
```

An inner class has full access to the members of its enclosing class, both static and instance. In particular, it can access private information, just as methods of the enclosing class can.

An inner class can have its own members. Inside instance methods of an inner class, `this` refers to the instance of the inner class. The instance of the outer class can be accessed as `Outer.this` (where `Outer` is the name of the outer class). If, for some dire reason, it is necessary to have an inner class within an inner class, the innermost class can refer to the `this` of either outer class by using its name.

An inner class can inherit from any class in scope, with no special restrictions. `super` inside an inner class refers to the inner class’s superclass. If it is necessary to refer to the outer classes’s superclass, use a qualified name of the form `Outer.super`.

The members of inner classes must be instance members. They cannot be static members. Classes, interfaces, static methods, static fields, and typedefs are not allowed as members of inner classes. The same restriction applies to local classes (§8.15).

Consider an inner class `IC1` of some outer class `OC1`, being extended by another class `IC2`. However, since an `IC1` only exists as a dependent of an `OC1`, each `IC2` must be associated with an `OC1` — or a subtype thereof — as well. So, `IC2` must be an inner class of either `OC1` or some subclass `OC2 <: OC1`. 
Example: For example, one often extends an inner class when one extends its outer class:

```java
class OC1 {
    class IC1 {}
}
class OC2 extends OC1 {
    class IC2 extends IC1 {}
}
```

The hiding of method names has one fine point. If an inner class defines a method named `doit`, then all methods named `doit` from the outer class are hidden — even if they have different argument types than the one defined in the inner class. They are still accessible via `Outer.this.doit()`, but not simply via `doit()`. The following code is correct, but would not be correct if the ERROR line were uncommented.

```java
class Outer {
    def doit() {}
    def doit(String) {}
    class Inner {
        def doit(Boolean, Outer) {}
        def example() {
            doit(true, Outer.this);
            Outer.this.doit();
            //ERROR: doit("fails")
        }
    }
}
```

### 8.14.1 Constructors and Inner Classes

If IC is an inner class of OC, then instance code in the body of OC can create instances of IC simply by calling a constructor `new IC(...)`:

```java
class OC {
    class IC {}
    def method(){
        val ic = new IC();
    }
}
```

Instances of IC can be constructed from elsewhere as well. Since every instance of IC is associated with an instance of OC, an OC must be supplied to the IC constructor. The syntax for doing so is: `OC.new IC()`. For example:

```java
class OC {
    class IC {}
}
```
static val oc1 = new OC();
static val oc2 = new OC();
static val ic1 = oc1.new IC();
static val ic2 = oc2.new IC();
}
class Elsewhere{
  def method(oc : OC) {
    val ic = oc.new IC();
  }
}

8.15 Local Classes

Classes can be defined and instantiated in the middle of methods and other code blocks. A local class in a static method is a static class; a local class in an instance method is an inner class. Local classes are local to the block in which they are defined. They have access to almost everything defined at that point in the method; the one exception is that they cannot use var variables. Local classes cannot be public, protected, or private, because they are only visible from within the block of declaration. They cannot be static.

Example: The following example illustrates the use of a local class Local, defined inside the body of method m().

class Outer {
  val a = 1;
  def m() {
    val a = -2;
    val b = 2;
    class Local {
      val a = 3;
      def m() = 100*Outer.this.a + 10*b + a;
    }
    val l : Local = new Local();
    assert l.m() == 123;
  }//end of m()
}

Note that the middle a, whose value is -2, is not accessible inside of Local; it is shadowed by Local’s a field. Outer’s a is also shadowed, but the notation Outer.this gives a reference to the enclosing Outer object. There is no corresponding notation to access shadowed local variables from the enclosing block; if you need to get them, rename the fields of Local.

The members of inner classes must be instance members. They cannot be static members. Classes, interfaces, static methods, static fields, and typedefs are not allowed as members of local classes. The same restriction applies to inner classes (§8.14).
8.16 Anonymous Classes

It is possible to define a new local class and instantiate it as part of an expression. The new class can extend an existing class or interface. Its body can include all of the usual members of a local class. It can refer to any identifiers available at that point in the expression — except for `var` variables. An anonymous class in a static context is a static inner class.

Anonymous classes are useful when you want to package several pieces of behavior together (a single piece of behavior can often be expressed as a function, which is syntactically lighter-weight), or if you want to extend and vary an extant class without going through the trouble of actually defining a whole new class.

The syntax for an anonymous class is a constructor call followed immediately by a braced class body: `new C(1) { def foo() = 2; }`.

**Example:** In the following minimalist example, the abstract class `Choice` encapsulates a decision. A `Choice` has a `yes()` and a `no()` method. The `choose(b)` method will invoke one of the two. Choices also have names.

The `main()` method creates a specific `Choice`. `c` is not a immediate instance of `Choice` — as an abstract class, `Choice` has no immediate instances. `c` is an instance of an anonymous class which inherits from `Choice`, but supplies `yes()` and `no()` methods. These methods modify the contents of the `Cell[Long] n`. (Note that, as `n` is a local variable, it would take a few lines more coding to extract `c`'s class, name it, and make it an inner class.) The call to `c.choose(true)` will call `c.yes()`, incrementing `n()`, in a rather roundabout manner:

```java
abstract class Choice(name: String) {
    def this(name: String) { property(name); }
    def choose(b: Boolean) {
        if (b) this.yes(); else this.no();
    }
    abstract def yes(): void;
    abstract def no(): void;
}

class Example {
    static def main(Rail[String]) {
        val n = new Cell[Long]()
        val c = new Choice("Inc Or Dec") {
            def yes() { n() += 1; }
            def no() { n() -= 1; }
        }
        c.choose(true);
        Console.OUT.println("n=\n" + n());
    }
}
```
Anonymous classes have many of the features of classes in general. A few features are unavailable because they don’t make sense.

- Anonymous classes don’t have constructors. Since they don’t have names, there’s no way a constructor could get called in the ordinary way. Instead, the new $C(...) \operatorname{expression}$ must match a constructor of the parent class $C$, which will be called to initialize the newly-created object of the anonymous class.

- The public, private, and protected modifiers don’t make sense for anonymous classes: Anonymous classes, being anonymous, cannot be referenced at all, so references to them can’t be public, private, or protected.

- Anonymous classes cannot be abstract. Since they only exist in combination with a constructor call, they must be constructable. The parent class of the anonymous class may be abstract, or may be an interface; in this case, the anonymous class must provide all the methods that the parent demands.

- Anonymous classes cannot have explicit extends or implements clauses; there’s no place in the syntax for them. They have a single parent and that is that.
9 Structs

X10 objects are a powerful general-purpose programming tool. However, the power must be paid for in space and time. In space, a typical object implementation requires some extra memory for run-time class information, as well as a pointer for each reference to the object. In time, a typical object requires an extra indirection to read or write data, and some run-time computation to figure out which method body to call.

For high-performance computing, this overhead may not be acceptable for all objects. X10 provides structs, which are stripped-down objects. They are less powerful than objects; in particular they lack inheritance and mutable fields. Without inheritance, method calls do not need to do any lookup; they can be implemented directly. Accordingly, structs can be implemented and used more cheaply than objects, potentially avoiding the space and time overhead. (Currently, the C++ back end avoids the overhead, but the Java back end implements structs as Java objects and does not avoid it.)

Structs and classes are interoperable. Both can implement interfaces; in particular, like all X10 values they implement Any. Subroutines whose arguments are defined by interfaces can take both structs and classes. (Some caution is necessary here: referring to a struct through an interface requires overhead similar to that required for an object.)

In many cases structs can be converted to classes or classes to structs, within the constraints of structs. If you start off defining a struct and decide you need a class instead, the code change required is simply changing the keyword struct to class. If you have a class that does not use inheritance or mutable fields, it can be converted to a struct by changing its keyword. Client code using the struct that was a class will need certain changes: e.g., the new keyword must be added in constructor calls, and structs (unlike classes) cannot be null.
9.1 Struct declaration

All fields of a struct must be `val`.

A struct `S` cannot contain a field of type `S`, or a field of struct type `T` which, recursively, contains a field of type `S`. This restriction is necessary to permit `S` to be implemented as a contiguous block of memory of size equal to the sum of the sizes of its fields.

Values of a struct `C` type can be created by invoking a constructor defined in `C`. Unlike for classes, the `new` keyword is optional for struct constructors.

**Example:** Leaving out `new` can improve readability in some cases:

```java
struct Polar(r:Double, theta:Double){
    def this(r:Double, theta:Double) {property(r,theta);}
    static val Origin = Polar(0,0);
    static val x0y1 = Polar(1, 3.14159/2);
    static val x1y0 = new Polar(1, 0);
}
```

When a struct and a method have the same name (often in violation of the X10 capitalization convention), `new` may be used to resolve to the struct’s constructor.

```java
struct Ambig(x:Long) {
    static def Ambig(x:Long) = "ambiguity please";
    static def example() {
        val useMethod = Ambig(1);
        val useConstructor = new Ambig(2);
    }
}
```

Structs support the same notions of generics, properties, and constrained types that classes do.

**Example:**

```java
struct Exam[T](nQuestions:Long){T <: Question} {
    public static interface Question {}
    // ...
}
```
## 9.2 Boxing of structs

If a struct \( S \) implements an interface \( I \) (e.g., \( \text{Any} \)), a value \( v \) of type \( S \) can be assigned to a variable of type \( I \). The implementation creates an object \( o \) that is an instance of an anonymous class implementing \( I \) and containing \( v \). The result of invoking a method of \( I \) on \( o \) is the same as invoking it on \( v \). This operation is termed *auto-boxing*. It allows full interoperability of structs and objects—at the cost of losing the extra efficiency of the structs when they are boxed.

In a generic class or struct obtained by instantiating a type parameter \( T \) with a struct \( S \), variables declared at type \( T \) in the body of the class are not boxed. They are implemented as if they were declared at type \( S \).

**Example:** The rail \( aa \) in the following example is a \( \text{Rail}[\text{Any}] \). It initially holds two objects. Then, its elements are replaced by two structs, both of which are auto-boxed. Note that no fussing is required to put an integer into a \( \text{Rail}[\text{Any}] \). However, a rail of structs, such as \( ah \), holds unboxed structs and does not incur boxing overhead.

```scala
def example()
val aa : Rail[\text{Any}] = ["a String" as \text{Any}, "another one"];
aa(0) = \text{Horse}(8);
aa(1) = 13;
val ah : Rail[\text{Horse}] = [\text{Horse}(7), \text{Horse}(13)];
```

### 9.3 Optional Implementation of \( \text{Any} \) methods

Two structs are equal (\( == \)) if and only if their corresponding fields are equal (\( == \)).

All structs implement \( \text{x10.lang.Any} \). Structs are required to implement the following methods from \( \text{Any} \). Programmers need not provide them; X10 will produce them automatically if the program does not include them.

```scala
public def equals(\text{Any}):\text{Boolean};
public def hashCode():\text{Int};
public def typeName():\text{String};
public def toString():\text{String};
```

A programmer who provides an explicit implementation of \( \text{equals}(\text{Any}) \) for a struct \( S \) should also consider supplying a definition for \( \text{equals}(S):\text{Boolean} \). This will often yield better performance since the cost of an upcast to \( \text{Any} \) and then a downcast to \( S \) can be avoided.
9.4 Primitive Types

Certain types that might be built in to other languages are in fact implemented as structs in package \texttt{x10.lang} in X10. Their methods and operations are often provided with \texttt{@Native} (§18) rather than X10 code, however. These types are:

- \texttt{Boolean}
- \texttt{Char}
- \texttt{Byte}
- \texttt{Short}
- \texttt{Int}
- \texttt{Long}
- \texttt{Float}
- \texttt{Double}
- \texttt{UByte}
- \texttt{UShort}
- \texttt{UInt}
- \texttt{ULong}

9.4.1 Signed and Unsigned Integers

X10 has an unsigned integer type corresponding to each integer type: \texttt{UInt} is an unsigned \texttt{Int}, and so on. These types can be used for binary programming, or when an extra bit of precision for counters or other non-negative numbers is needed in integer arithmetic. However, X10 does not otherwise encourage the use of unsigned arithmetic.

9.5 Example structs

\texttt{x10.lang.Complex} provides a detailed example of a practical struct, suitable for use in a library. For a shorter example, we define the \texttt{Pair} struct. A \texttt{Pair} packages two values of possibly unrelated type together in a single value, \textit{e.g.}, to return two values from a function.

\texttt{divmod} computes the quotient and remainder of \(a \div b\) (naively). It returns both, packaged as a \texttt{Pair[UInt, UInt]}. Note that the constructor uses type inference, and that the quotient and remainder are accessed through the \texttt{first} and \texttt{second} fields.

```scala
struct Pair[T,U] {
    public val first:T;
    public val second:U;
    public def this(first:T, second:U):Pair[T,U] {
        this.first = first;
        this.second = second;
    }
    public def toString() = "(" + first + ", " + second + ")";
}

class Example {
    static def divmod(var a:UInt, b:UInt): Pair[UInt, UInt] {
        assert b > 0u;
        var q : UInt = 0un;
        while (a > b) {q += 1un; a -= b;}
        return Pair(q, a);
    }
```
9.6 Nested Structs

Static nested structs may be defined, essentially as static nested classes except for making them structs (§8.13). Inner structs may be defined, essentially as inner classes except making them structs (§8.14). **Limitation:** Nested structs must be currently be declared static.

9.7 Default Values of Structs

If all fields of a struct have default values, then the struct has a default value, *viz.*, the struct whose fields are all set to their default values. If some field does not have a default value, neither does the struct.

**Example:**

In the following code, the `Example` struct has a default value whose `i` field is 0. If an `Example` is ever constructed by the constructor, its `i` field will be 1. This program does a slightly subtle dance to get ahold of a default `Example`, by having an instance `var` (which, unlike most kinds of variables, does not need to get initialized before use (though that exemption only applies if its type has a default value)). As the `assert` confirms, the default `Example` does indeed have an `i` field of 0.

```scala
class StructDefault {
  static struct Example {
    val i : Long;
    def this() { i = 1; }
  }
  var ex : Example;
  static def example() {
    val ex = (new StructDefault()).ex;
    assert ex.i == 0;
  }
}
```

9.8 Converting Between Classes And Structs

Code written using structs can be modified to use classes, or vice versa. Caution must be used in certain places.
Class and struct definitions are syntactically nearly identical: change the `class` keyword to `struct` or vice versa. Of course, certain important class features can’t be used with structs, such as inheritance and `var` fields.

Converting code that uses the class or struct requires a certain amount of caution. Suppose, in particular, that we want to convert the class `Class2Struct` to a struct, and `Struct2Class` to a class.

```scala
class Class2Struct {
  val a : Long;
  def this(a:Long) { this.a = a; }
  def m() = a;
}
struct Struct2Class {
  val a : Long;
  def this(a:Long) { this.a = a; }
  def m() = a;
}
```

1. Class constructors require the `new` keyword; struct constructors allow it but do not require it. `Struct2Class(3)` to will need to be converted to `new Struct2Class(3)`.

2. Objects and structs have different notions of `==`. For objects, `==` means “same object”; for structs, it means “same contents”. Before conversion, both asserts in the following program succeed. After converting and fixing constructors, both of them fail.

```scala
val a = new Class2Struct(2);
val b = new Class2Struct(2);
assert a != b;
val c = Struct2Class(3);
val d = Struct2Class(3);
assert c==d;
```

3. Objects can be set to `null`. Structs cannot.

4. The rules for default values are quite different. The default value of an object type (if it exists) is `null`, which behaves quite differently from an ordinary object of that type; e.g., you cannot call methods on `null`, whereas you can on an ordinary object. The default value for a struct type (if it exists) is a struct like any other of its type, and you can call methods on it as for any other.
10 Functions

10.1 Overview

Functions, the last of the three kinds of values in X10, encapsulate pieces of code which can be applied to a vector of arguments to produce a value. Functions, when applied, can do nearly anything that any other code could do: fail to terminate, throw an exception, modify variables, spawn activities, execute in several places, and so on. X10 functions are not mathematical functions: the \( f(1) \) may return \( \text{true} \) on one call and \( \text{false} \) on an immediately following call.

A function literal \( (x_1:T_1, \ldots, x_n:T_n)\{c}\):T=>e creates a function of type \( (x_1:T_1, \ldots, x_n:T_n)\{c\}=>T \) ([4.6]). For example, \( (x:\text{Long}):\text{Long} => x^x \) is a function literal describing the squaring function on integers. Every function type also possesses the (default) value \( \text{null} \).

Limitation: X10 functions cannot have type arguments or constraints.

Function application is written \( f(a,b,c) \), following common mathematical usage.

The function body may be a block. To compute integer squares by repeated addition (inefficiently), one may write:

```scala
val sq: (Long) => Long = (n:Long) => {
  var s : Long = 0;
  val abs_n = n < 0 ? -n : n;
  for (i in 1..abs_n) s += abs_n;
  s
};
```

A function literal evaluates to a function entity \( f \). When \( f \) is applied to a suitable list of actual parameters \( a_1 \) through \( a_n \), it evaluates \( e \) with the formal parameters bound to the actual parameters. So, the following are equivalent, where \( e \) is an expression involving \( x_1 \) and \( x_2 \)

```scala
var result:T;
{
  val f = (x1:T1,x2:T2){true}:T => e;
}
```
\begin{verbatim}
val a1 : T1 = arg1();
val a2 : T2 = arg2();
result = f(a1,a2);
\}

and

var result:T;
{  
val a1 : T1 = arg1();
val a2 : T2 = arg2();
{  
val x1 : T1 = a1;
val x2 : T2 = a2;
result = e;
}
}
\end{verbatim}

This equivalence does not hold if the body is a statement rather than an expression. A few language features are forbidden (break or continue of a loop that surrounds the function literal) or mean something different (return inside a function returns from the function, not the surrounding block).

Function types may be used in implements clauses of class definitions. Suitable operator definitions must be supplied, with public operator this(x1:T1, ..., xn:Tn) declarations. Instances of such classes may be used as functions of the given type. Indeed, an object may behave like any (fixed) number of functions, since the class it is an instance of may implement any (fixed) number of function types. e.g. Instances of the Funny class behave like two functions: a constant function on Booleans, and a linear function on pairs of Longs.

\begin{verbatim}
class Funny implements (Boolean) => Long,
   (Long, Long) => Long
{  
   public operator this(Boolean) = 1;
   public operator this(x:Long, y:Long) = 10*x+y;
   static def example() {
      val f <: Funny = new Funny();
      assert f(true) == 1; // (Boolean)=>Long behavior
      assert f(1,2) == 12; // (Long,Long)=>Long behavior
   }
}
\end{verbatim}

### 10.2 Function Application

The basic operation on functions is function application. (Since, e.g., array lookup has the same type as function application, these rules are used for array lookup as well, and
10.3 Function Literals

so on.)

A function with type \((x_1:T_1, \ldots, x_n:T_n)\{c\} \Rightarrow T\) can be applied to a sequence of expressions \(e_1, \ldots, e_n\) if:

- \(e_1\) is of type \(T_1[e_1/x_1]\),
- \(\ldots\),
- \(e_n\) is of type \(T_n[e_1/x_1, \ldots, e_n/x_n]\),
- X10 can prove that \(c[e_1/x_1, \ldots, e_n/x_n]\) holds.

In this case, if the application terminates normally, it returns a value of type \(T[y_1/x_1, \ldots, y_n/x_n]\) where \(y_1, \ldots, y_n\) may be thought of as new variables defined as if by:

\[
\begin{align*}
\text{val } y_1 &= e_1; \\
\ldots \\
\text{val } y_n &= e_n;
\end{align*}
\]

Example: Consider

\[
f : (a:Long\{a!=0\}, \ b:Long\{b!=a\})\{b!=0\} \Rightarrow Long\{self != a\}
\]

Then the call \(f(3,4)\) is allowed, because:

- \(3\) is of type \(Long\{a!=0\}\) with \(a\) replaced by 3, viz. \(Long\{3 \neq 0\}\);
- \(4\) is of type \(Long\{b!=a\}\) with \(a\) replaced by 3 and \(b\) replaced by 4, viz. \(Long\{3 \neq 4\}\).
- The guard \(b!=0\), with \(a\) replaced by 3 and \(b\) replaced by 4, is \(4!=0\), which is true.

So, \(f(3,4)\) will return a value of type \(Long\{self != a\}\) with \(a\) replaced by 3 and \(b\) replaced by 4, which is to say, \(Long\{self!=3\}\).

10.3 Function Literals

X10 provides first-class, typed functions, often called closures.

\[
\begin{align*}
\text{ClosureExp} & ::= \text{Formals Guard}^1 \text{HasResultType}^2 \Rightarrow \text{ClosureBody} \\
\text{Formals} & ::= (\text{FormalList}^1) \\
\text{Guard} & ::= \text{DepParams} \\
\text{HasResultType} & ::= \text{ResultType} \\
& \quad | \quad <: \text{Type} \\
\text{ClosureBody} & ::= \text{Exp} \\
& \quad | \quad \text{ClosureBodyBlock} \\
\text{ClosureBodyBlock} & ::= \text{Annotations}^1 \{\text{BlockStmts}^2 \text{LastExp}\} \\
& \quad | \quad \text{Annotations}^1 \text{Block}
\end{align*}
\]
Functions have zero or more formal parameters and an optional return type. The body has the same syntax as a method body; it may be either an expression, a block of statements, or a block terminated by an expression to return. Return statements may be used in the body of the function to return a value (§12.13).

The type of a function is a function type as described in §4.6. In some cases the return type $T$ of the function can be omitted and defaults to the type of the body. If a formal $x_i$ does not occur in any $T_j$, $c$, $T$ or $e$, the declaration $x_i: T_i$ may be replaced by just $T_i$. E.g., $(\text{Long}) => 7$ is the integer function returning 7 for all inputs.

As with methods, a function may declare a guard to constrain the actual parameters with which it may be invoked. The guard may refer to the type parameters, formal parameters, and any vals in scope at the function expression.

**Example:**

```scala
val n = 3;
val f : (x:Long){x != n} => Long
  = (x:Long){x != n} => (12/(n-x));
Console.UT.println("f(5)=" + f(5));
```

The body of the function is evaluated when the function is invoked by a call expression (§11.6), not at the function’s place in the program text.

As with methods, a function with return type $\text{void}$ cannot have a terminating expression. If the return type is omitted, it is inferred, as described in §4.12. It is a static error if the return type cannot be inferred. E.g., $(\text{Long}) => \text{null}$ is not well-specified; X10 does not know which type of $\text{null}$ is intended. But $(\text{Long}):\text{Rail}[\text{Double}] => \text{null}$ is legal.

**Example:** The following method takes a function parameter and uses it to test each element of the list, returning the first matching element. It returns $\text{no}$ if no element matches.

```scala
def find[T](f: (T) => Boolean, xs: List[T], no:T): T {
  for (x: T in xs)
    if (f(x)) return x;
return no;
}
```

The method may be invoked thus, to find a positive element of $\text{x}_s$, or return $\text{0}$ if there is no positive element.

```scala
xs: List[Long] = new ArrayList[Long]();
xs: Long = find((x: Long) => x>0, xs, 0);
```

### 10.3.1 Outer variable access

In a function $(x_1: T_1, \ldots, x_n: T_n){c} => \{ s \}$ the types $T_i$, the guard $c$ and the body $s$ may access the following variables from outer scopes:
10.4. FUNCTIONS AS OBJECTS OF TYPE Any

- All fields of the enclosing object(s) and class(es);
- All type parameters;
- All val variables;

val variables cannot be accessed.

The function body may refer to instances of enclosing classes using the syntax C.this, where C is the name of the enclosing class. this refers to the instance of the immediately enclosing class, as usual.

e.g. The following is legal. Note that a is not a local var variable. It is a field of this. A reference to a is simply short for this.a, which is a use of a val variable (this).

```scala
class Lambda {
  var a : Long = 0;
  val b = 0;
  def m(var c : Long, val d : Long) {
    var e : Long = 0;
    val f : Long = 0;
    val closure = (var i: Long, val j: Long) => {
      // c and e are not usable here
      a + b + d + f + i
      + j + this.a + Lambda.this.a
    };
    return closure;
  }
}
```

10.4 Functions as objects of type Any

Two functions \( f \) and \( g \) are equal if both were obtained by the same evaluation of a function literal. Further, it is guaranteed that if two functions are equal then they refer to the same locations in the environment and represent the same code, so their executions in an identical situation are indistinguishable. (Specifically, if \( f == g \), then \( f(1) \) can be substituted for \( g(1) \) and the result will be identical. However, there is no guarantee that \( f(1)==g(1) \) will evaluate to true, since there is no guarantee that \( f(1)==f(1) \) will evaluate to true either, as \( f \) might be a function which returns \( n \) on its \( n^{th} \) invocation. However, \( f(1)==f(1) \) and \( f(1)==g(1) \) are interchangeable.)

Every function type implements all the methods of Any. \( f.equals(g) \) is equivalent to \( f==g \). The behavior of hashCode, toString, and typeName is up to the implementation, but respect equals and the basic contracts of Any.

---

\(^1\) A literal may occur in program text within a loop, and hence may be evaluated multiple times.
11 Expressions

X10 has a rich expression language. Evaluating an expression produces a value, or, in a few cases, no value. Expression evaluation may have side effects, such as change of the value of a var variable or a data structure, allocation of new values, or throwing an exception.

11.1 Literals

Literals denote fixed values of built-in types. The syntax for literals is given in §3.5.

The type that X10 gives a literal often includes its value. E.g., 1 is of type Long{self==1}, and true is of type Boolean{self==true}.

11.2 this

\[
\text{Primary} \ ::= \ \text{this} \quad \text{(20.138)} \\
| \quad \text{ClassName} . \ \text{this}
\]

The expression this is a local val containing a reference to an instance of the lexically enclosing class. It may be used only within the body of an instance method, a constructor, or in the initializer of an instance field – that is, the places where there is an instance of the class under consideration.

Within an inner class, this may be qualified with the name of a lexically enclosing class. In this case, it represents an instance of that enclosing class.

Example: Outer is a class containing Inner. Each instance of Inner has a reference Outer.this to the Outer involved in its creation. Inner has access to the fields of Outer.this. Note that Inner has its own three field, which is different from and not even the same type as Outer.this.three.

```java
class Outer {
    val three = 3;
    class Inner {
        val three = 3;
    }
}
```
11.3 Local variables

Id ::= IDENTIFIER \[20.90\]

A local variable expression consists simply of the name of the local variable, a field of this, a formal parameter in scope, etc. It evaluates to the value of the local variable.

Example: \texttt{n} in the second line below is a local variable expression. The \texttt{n} in the first line is not; it is part of a local variable declaration.

\begin{verbatim}
val n = 22;
val m = n + 56;
\end{verbatim}

11.4 Field access

FieldAccess ::= Primary . Id | super . Id | ClassName . super . Id \[20.67\]

A field of an object instance may be accessed with a field access expression.

The type of the access is the declared type of the field with the actual target substituted for this in the type.

Example: The declaration of \texttt{b} below has a constraint involving \texttt{this}. The use of an instance of it, \texttt{f.b}, has the same constraint involving \texttt{f} instead of \texttt{this}, as required.
class Fielded {
    public val a : Long = 1;
    public val b : Long{this.a == b} = this.a;
    static def example() {
        val f : Fielded = new Fielded();
        assert f.a == 1 && f.b == 1;
        val fb : Long{fb == f.a} = f.b;
        assert fb == 1;
    }
}

The field accessed is selected from the fields and value properties of the static type of
the target and its superclasses.

If the field target is given by the keyword super, the target’s type is the superclass of
the enclosing class. This form is used to access fields of the parent class hidden by
same-named fields of the current class.

If the field target is Cls.super, then the target’s type is Cls, which must be an enclos-
ing class. This (admittedly obscure) form is used to access fields of an ancestor class
which are shadowed by same-named fields of some more recent ancestor.

Example: This illustrates all four cases of field access.

class Uncle {
    public static val f = 1;
}
class Parent {
    public val f = 2;
}
class Ego extends Parent {
    public val f = 3;
}
class Child extends Ego {
    public val f = 4;
    def example() {
        assert Uncle.f == 1;
        assert Ego.super.f == 2;
        assert super.f == 3;
        assert this.f == 4;
        assert f == 4;
    }
}

If the field target is null, a NullPointerException is thrown. If the field target is a
class name, a static field is selected. It is illegal to access a field that is not visible from
the current context. It is illegal to access a non-static field through a static field access
expression. However, it is legal to access a static field through a non-static reference.
11.5 Function Literals

Function literals are described in §10.

11.6 Calls

MethodInvo ::= MethodName TypeArgs? (ArgumentList?)
| Primary . Id TypeArgs? (ArgumentList?)
| super . Id TypeArgs? (ArgumentList?)
| ClassName . super . Id TypeArgs? (ArgumentList?)
| Primary TypeArgs? (ArgumentList?)

ArgumentList ::= Exp
| ArgumentList , Exp

MethodName ::= Id
| FullyQualifiedId . Id

A MethodInvocation may be to either a static method, an instance method, or a closure.

The syntax for method invocations is ambiguous. ob.m() could either be the invocation of a method named m on object ob, or the application of a function held in a field ob.m. If both are defined on the same class, X10 resolves ob.m() to the invocation of the method. If the application of a function in a field is desired, use an alternate syntax which makes the intent clear to X10, such as (ob.m)().

Example:

```scala
class Callsome {
  static val closure : () => Long = () => 1;
  static def method() = 2;
  static def example() {
    assert Callsome.closure() == 1;
    assert Callsome.method() == 2;
  }
}
```

However, adding a static method [mis]named closure makes Callsome.closure() refer to the method, rather than the closure

```scala
static def closure () = 3;
static def example() {
  assert Callsome.closure() == 3;
  assert (Callsome.closure)() == 1;
}
```

The application form e(f,g), when e evaluates to an object or struct, invokes the application operator, defined in the form
public operator this(f:F, g:G) = "value";

Method selection rules are given in §8.12.

Guard satisfaction depends on the STATIC_CHECKS compiler flag. With the flag on, it is a static error if a method’s Guard is not statically satisfied by the caller. With STATIC_CHECKS off, the guard will be checked at runtime if necessary.

**Example:** In this example, a DivideBy object provides the service of dividing numbers by denom — so long as denom is not zero. X10’s strictness of checking this is under control of the STATIC_CHECKS compiler option (§C.1.3).

With STATIC_CHECKS turned on, the example method will not compile. The call this.div(100) is not allowed; there is no guarantee that denom != 0. Casting this to a type whose constraint implies denom != 0 permits the method call.

With STATIC_CHECKS turned off, the call will compile. X10 will insert a dynamic check that the denominator is non-zero, and will fail at runtime if it is zero.

```scala
class DivideBy(denom:Long) {
  def div(numer:Long) {denom != 0} = numer / denom;
  def example() {
    val thisCast = (this as DivideBy{self.denom != 0});
    thisCast.div(100);
    //ERROR (with STATIC_CHECKS): this.div(100);
  }
}
```

### 11.6.1 super calls

The expression super.f(e1...en) may appear in an instance method definition. This causes the method invocation to be a super invocation, as described in §8.12.

Informally, suppose the invocation appears in class Cl, which extends class Sup. An invocation this.f() will call a nullary method named f that appears in class Cl itself, if there is one. An invocation super.f() will call the nullary f method in Sup or an ancestor thereof, but not one in Cl. Note that super.f() may be used to invoke an f method in Sup which has been overridden by one appearing in Cl.

Note that there’s only one choice for which f is invoked by super.f() — viz. the lowest one in the class hierarchy above Cl. So, super.f() performs static dispatch, like a static method call. This is generally more efficient than a dynamic dispatch, like an instance method call.
The assignment expression \( x = e \) assigns a value given by expression \( e \) to a variable \( x \). Most often, \( x \) is mutable, a var variable. The same syntax is used for delayed initialization of a val, but vals can only be initialized once.

```
var x : Long;
val y : Long;
x = 1;
y = 2; // Correct; initializes y
x = 3;
// ERROR: y = 4;
```

There are three syntactic forms of assignment:

1. \( x = e \);, assigning to a local variable, formal parameter, field of this, etc.
2. \( x.f = e \);, assigning to a field of an object.
3. \( a(i_1, \ldots, i_n) = v \);, where \( n \geq 0 \), assigning to an element of an array or some other such structure. This is an operator call (§8.7). For well-behaved classes it works like array assignment, mutatis mutandis, but there is no actual guarantee, and the compiler makes no assumptions about how this works for arbitrary \( a \). Naturally, it is a static error if no suitable assignment operator for \( a \) exists..

For a binary operator \( \diamond \), the \( \diamond \)-assignment expression \( x \diamond= e \) combines the current value of \( x \) with the value of \( e \) by \( \diamond \), and stores the result back into \( x \). \( i += 2 \), for example, adds 2 to \( i \). For variables and fields,
\( x \circ e \)

behaves just like

\[ x = x \circ e. \]

The subscripting forms of \( a(i) \circ b \) are slightly subtle. Subexpressions of \( a \) and \( i \) are only evaluated once. However, \( a(i) \) and \( a(i) = c \) are each executed once—in particular, there is one call to the application operator, and one to the assignment operator. If subscripting is implemented strangely for the class of \( a \), the behavior is not necessarily updating a single storage location. Specifically, \( A() I() += B() \) is tantamount to the following code, except for the unspecified order of evaluation of the expressions:

\[
\{
// The order of these evaluations is not specified
val aa = A(); // Evaluate A() once
val ii = I(); // Evaluate I() once
val bb = B(); // Evaluate B() once
// But they happen before this:
val tmp = aa(ii) + bb; // read aa(ii)
    aa(ii) = tmp; // write sum back to aa(ii)
\}
\]

### 11.8 Increment and decrement

The operators \( ++ \) and \( -- \) increment and decrement a variable, respectively. \( x++ \) and \( ++x \) both increment \( x \), just as the statement \( x += (1 \text{ as } T) \) would (where \( x:T \)), and similarly for \( -- \).

The difference between the two is the return value. \( ++x \) and \( --x \) return the new value of \( x \), after incrementing or decrementing. \( x++ \) and \( x-- \) return the old value of \( x \), before incrementing or decrementing.

These operators work for any \( x \) for which \( 1 \text{ as } T \) is defined, where \( T \) is the type of \( x \).

### 11.9 Numeric Operations

Numeric types (\( \text{Byte, Short, Int, Long, Float, Double, Complex} \), and unsigned variants of fixed-point types) are normal X10 structs, though most of their methods are implemented via native code. They obey the same general rules as other X10 structs. For example, numeric operations, coercions, and conversions are defined by operator definitions, the same way you could for any struct.
11.10. **BITWISE COMPLEMENT**

Promoting a numeric value to a longer numeric type results in either sign extension or zero extension depending on whether the target type is signed or unsigned. For example, \((255 \text{ as } \text{UByte}) \text{ as } \text{UInt}\) is 255 while \((255 \text{ as } \text{Byte}) \text{ as } \text{Int}\) is -1.

Most of these operations can be defined on user-defined types as well. While it is good practice to keep such operations consistent with the numeric operations whenever possible, the compiler neither enforces nor assumes any particular semantics of user-defined operations.

### 11.9.1 Conversions and coercions

Specifically, each numeric type can be converted or coerced into each other numeric type, perhaps with loss of accuracy.

**Example:**

```scala
val n : Byte = 123 as Byte; // explicit
val f : (Long)=>Boolean = (Long) => true;
val ok = f(n); // implicit
```

### 11.9.2 Unary plus and unary minus

The unary `+` operation on numbers is an identity function. The unary `-` operation on signed numbers is a negation function. On unsigned numbers, these are two’s-complement arithmetic; the unsigned number types are closed under unary `-`. For example, \(-0x0F \text{ as } \text{UByte}\) is \(0xF1 \text{ as } \text{UByte}\).

### 11.10 Bitwise complement

The unary `˜` operator, only defined on integral types, complements each bit in its operand.

### 11.11 Binary arithmetic operations

The binary arithmetic operators perform the familiar binary arithmetic operations: `+` adds, `-` subtracts, `*` multiplies, `/` divides, and `%` computes remainder.

On integers, the operands are coerced to the longer of their two types, and then operated upon. Floating point operations are determined by the IEEE 754 standard. The integer `/` and `%` throw an exception if the right operand is zero.
11.12 Binary shift operations

When operands of the binary shift operations are of integral type, the expression performs bitwise shifts. The type of the result is the type of the left operand. The right operand, describing a number of bits, must be a Long: x << y.

If the promoted type of the left operand is Int, the right operand is masked with 0x1f using the bitwise AND (&) operator, giving a number at most the number of bits in an Int. If the promoted type of the left operand is Long, the right operand is masked with 0x3f using the bitwise AND (&) operator, giving a number at most the number of bits in a Long.

The << operator left-shifts the left operand by the number of bits given by the right operand. The >> operator right-shifts the left operand by the number of bits given by the right operand. The result is sign extended; that is, if the right operand is k, the most significant k bits of the result are set to the most significant bit of the operand.

The >>> operator right-shifts the left operand by the number of bits given by the right operand. The result is not sign extended; that is, if the right operand is k, the most significant k bits of the result are set to 0. This operation is deprecated, and may be removed in a later version of the language.

11.13 Binary bitwise operations

The binary bitwise operations operate on integral types, which are promoted to the longer of the two types. The & operator performs the bitwise AND of the promoted operands. The | operator performs the bitwise inclusive OR of the promoted operands. The ^ operator performs the bitwise exclusive OR of the promoted operands.

11.14 String concatenation

The + operator is used for string concatenation as well as addition. If either operand is of static type x10.lang.String, the other operand is converted to a String, if needed, and the two strings are concatenated. String conversion of a non-null value is performed by invoking the toString() method of the value. If the value is null, the value is converted to "null".

The type of the result is String.

For example, "one " + 2 + true evaluates to one 2true.

11.15 Logical negation

The unary ! operator applied to type x10.lang.Boolean performs logical negation. The type of the result is Boolean. If the value of the operand is true, the result is false; if if the value of the operand is false, the result is true.
11.16 Boolean logical operations

The binary operations & and | at type Boolean perform Boolean logical operations. The & operator evaluates to true if both of its operands evaluate to true; otherwise, the operator evaluates to false.

The | operator evaluates to false if both of its operands evaluate to false; otherwise, the operator evaluates to true.

11.17 Boolean conditional operations

The binary && and || operations, on Boolean values, give conditional or short-circuiting Boolean operations. The && operator evaluates to true if both of its operands evaluate to true; otherwise, the operator evaluates to false. Unlike the logical operator &, if the first operand is false, the second operand is not evaluated.

The || operator evaluates to false if both of its operands evaluate to false; otherwise, the operator evaluates to true. Unlike the logical operator ||, if the first operand is true, the second operand is not evaluated.

11.18 Relational operations

The relational operations on numeric types compare numbers, producing Boolean results. The < operator evaluates to true if the left operand is less than the right. The <= operator evaluates to true if the left operand is less than or equal to the right. The > operator evaluates to true if the left operand is greater than the right. The >= operator evaluates to true if the left operand is greater than or equal to the right.

Floating point comparison is determined by the IEEE 754 standard. Thus, if either operand is NaN, the result is false. Negative zero and positive zero are considered to be equal. All finite values are less than positive infinity and greater than negative infinity.

11.19 Conditional expressions

\[ \text{ConditionalExp} \ ::= \text{ConditionalOrExp} \ ? \ Exp : \text{ConditionalExp} \]

A conditional expression evaluates its first subexpression (the condition); if true the second subexpression (the consequent) is evaluated; otherwise, the third subexpression (the alternative) is evaluated.
The type of the condition must be Boolean. The type of the conditional expression is some common ancestor (as constrained by \([4.10]\)) of the types of the consequent and the alternative.

**Example:**  
\[ a == b ? 1 : 2 \] evaluates to 1 if \( a \) and \( b \) are the same, and 2 if they are different. As the type of 1 is Long{self=1} and of 2 is Long{self=2}, the type of the conditional expression has the form Long{c}, where self=1 and self=2 both imply c. For example, it might be Long{true} – or perhaps it might be a more accurate type, like Long{self != 8}. Note that this term has no most accurate type in the X10 type system.

The subexpression not selected is not evaluated.

**Example:**  
The following use of the conditional expression prevents division by zero. If \( \text{den}==0 \), the division is not performed at all.

\[ (\text{den} == 0) ? 0 : \text{num}/\text{den} \]

Similarly, the following code performs a method call if \( \text{op} \) is non-null, and avoids the null pointer error if it is null. Defensive coding like this is quite common when working with possibly-null objects.

\[ (\text{ob} == \text{null}) ? \text{null} : \text{ob}.\text{toString}(); \]

### 11.20 Stable equality

\[
\text{EqualityExp} \ ::= \ \text{RelationalExp} \quad (20.59) \\
\text{EqualityExp} == \text{RelationalExp} \\
\text{EqualityExp} != \text{RelationalExp} \\
\text{Type} == \text{Type}
\]

The == and != operators provide a fundamental, though non-abstract, notion of equality. \( a==b \) is true if the values of \( a \) and \( b \) are extremely identical.

- If \( a \) and \( b \) are values of object type, then \( a==b \) holds if \( a \) and \( b \) are the same object.
- If one operand is null, then \( a==b \) holds iff the other is also null.
- The structs in \texttt{x10.lang} have unsurprising concepts of ==:
  - In Boolean, \texttt{true == true} and \texttt{false == false}.
  - In Char, \texttt{c == d if c.\texttt{ord}() == d.\texttt{ord}()}.
  - Equality in Double and Float is IEEE floating-point equality.
  - Two GlobalRefs are == if they refer to the same object.
11.20. **STABLE EQUALITY**

- The integral types, `Byte`, `Short`, `Int`, `Long`, and their unsigned versions, use binary equality.

  • If the operands both have struct type and are not in `x10.lang`, then they must be structurally equal; that is, they must be instances of the same struct and all their fields or components must be `==`.

  • The definition of equality for function types is specified in §10.4.

  • No implicit coercions are performed by `==`.

  • It is a static error to have an expression `a == b` if the types of `a` and `b` are disjoint.

\[ a \neq b \] is true iff `a==b` is false.

The predicates `==` and `!=` may not be overridden by the programmer.

`==` provides a *stable* notion of equality. If two values are `==` at any time, they remain `==` forevermore, regardless of what happens to the mutable state of the program.

**Example:** Regardless of the values and types of `a` and `b`, or the behavior of `any_code_at_all` (which may, indeed, be any code at all—not just a method call), the value of `a==b` does not change:

```x10
val a = something();
val b = something_else();
val eq1 = (a == b);
any_code_at_all();
val eq2 = (a == b);
assert eq1 == eq2;
```

11.20.1 **No Implicit Coercions for `==`**

`==` is a primitive operation in X10—one of very few. Most operations, like `+` and `<=`, are defined as *operators*. `==` and `!=` are not. As non-operators, they need not and do not follow the general method resolution procedure of §8.12. In particular, while *operators* perform implicit conversions on their arguments, `==` and `!=` do not.

The advantage of this restriction is that `==`’s behavior is as simple and efficient as possible. It never runs user-defined code, and the compiler can analyze and understand it in detail—and guarantee that it is efficient.

The disadvantage is that certain straightforward-looking idioms do not work. One may not test that an `Int` variable is `==` to a long like `0`:

```x10
//ERROR: for(var i : Int = 0n; i != 100; i++) {} 
```

A `Int` like `i` can never `==` a `Long` like `100`. Because `==` does not permit implicit coercions, `i` stays a `Int`. The loop must be written with a comparison of two `Int`s:

```x10
for(var i : Int = 0n; i != 100n; i++) {} 
```
Because the operation $\leq$ is a regular operator, and thus uses coercions in its arguments, it is legal (although not recommended) to write the loop as

```plaintext
for(var i : Int = 0n; i <= 100; i++) {}
```

In this formulation, `i` will be coerced to a `Long` on each loop iteration so it can be compared using $\leq$ against `100`.

**Example:** If numbers are cast to `Any`, they are compared as values of type `Any`, not as numbers. For example, `1 as Any == 1ul as Any` is not a static error (because it is comparing two values of type `Any`), and returns `false` (because the two `Any` values refer to different values — indeed, to values of different types, `Int` and `ULong`).

### 11.20.2 Non-Disjointness Requirement

It is, in many cases, a static error to have an expression `a==b` where `a` and `b` could not possibly be equal, based on their types. (In one case it is a static error even though they *could* be equal.) This is a practical codicil to §11.20.1. Consider the illegal code

```plaintext
// NOT ALLOWED
for(var i : Long = 0; i != 100; i++)
```

`100` and `100L` are different values; they are not `==`. A coercion could make them equal, but `==` does not allow coercions. So, if `100 == 100L` were going to return anything, it would have to return `false`. This would have the unfortunate effect of making the `for` loop run forever.

Since this and related idioms are so common, and since so many programmers are used to languages which are less precise about their numeric types, X10 avoids the mistake by declaring it a static error in most cases. Specifically, `a==b` is not allowed if, by inspection of the types, `a` and `b` could not possibly be equal.

**Example:** Nonetheless, it is possible to wind up comparing values of different numeric types. Even though, say, `0n` and `0L` represent the same number, they are different values and of different types, and hence, `0n != 0L`. The expression `0n == 0L` does not compile. However, if you hide type information from X10, you can get a similar expression to compile:

```plaintext
val a : Any = 0n;
val b : Any = 0L;
assert a != b;
```

- Numbers of different base types cannot be equal, and thus cannot compared for equality. `100==100L` is a static error. To compare numbers, explicitly cast them to the same type: `100 as Long == 100L`.
- Indeed, structs of different types cannot be equal, and so they cannot be compared for equality.
• For objects, the story is different. Unconstrained object types can always be compared for equality. Given objects of unrelated classes \(a: \text{Person} \) and \(b: \text{Theory} \), \(a==b\) could be true if \(a==null\) and \(b==null\). Despite this, \(a==b\) is a static error, because it is generally a programming mistake. \(a \text{ as } \text{Any} == b \text{ as } \text{Any}\) can be used to express the equality, if it is necessary.

• Constraints are ignored in determining whether an equality is statically allowed. For example, the following is allowed:

\[
def \text{m}(a:\text{Long}\{\text{self}==1\}, b:\text{Long}\{\text{self}==2\}) = (a==b);
\]

• Explicit casts erase type information. If you wanted to have a comparison \(a==b\) for \(a: \text{Person}\{\text{self}!=null\}\) and \(b: \text{Theory}\), you could write it as \(a \text{ as } \text{Any} == b \text{ as } \text{Any}\). It would, of course, return \(false\), but it would not be a compiler error.\(^1\) A struct and an object may both be cast to \(\text{Any}\) and compared for equality, though they, too, will always be different.

11.21 Allocation

An allocation expression creates a new instance of a class and invokes a constructor of the class. The expression designates the class name and passes type and value arguments to the constructor.

The allocation expression may have an optional class body. In this case, an anonymous subclass of the given class is allocated. An anonymous class allocation may also specify a single super-interface rather than a superclass; such an anonymous class does not have a superclass.

If the class is anonymous—that is, if a class body is provided—then the constructor is selected from the superclass. The constructor to invoke is selected using the same rules as for method invocation (§11.6).

The type of an allocation expression is the return type of the constructor invoked, with appropriate substitutions of actual arguments for formal parameters, as specified in §11.6.

§8.14.1 describes allocation expressions for inner classes.

It is illegal to allocate an instance of an abstract class. The usual visibility rules apply to allocations: it is illegal to allocate an instance of a class or to invoke a constructor that is not visible at the allocation expression.

Note that instantiating a struct type can use function application syntax; \(\text{new}\) is optional. As structs do not have subclassing, there is no need or possibility of a ClassBody.

\(^1\)Code generators often find this trick to be useful.
11.22 Casts and Conversions

The cast and conversion operation \( e \text{ as } T \) may be used to force an expression into a given type \( T \), if is permissible at run time, and either a compile-time error or a runtime exception (\texttt{x10.lang.ClassCastException}) if it is not.

The \( e \text{ as } T \) operation comes in two forms. Which form applies depends on both the source type (the type of \( e \)) and the target type \( T \).

- **Cast**: A cast makes a value have a different type, without changing the value’s identity. For example, "a String" as Any simply reconsiders the String object as an Any. This cast does not need to do any run-time computation, since every String is an Any; a cast in the reverse direction, from Any to String, would need a run-time check that the Any was in fact a String. Casts are all system-defined, following from the X10 type system.

- **Conversions**: A conversion takes a value of one type and produces one of a different type which, conceptually, means the same thing. For example, 1 as Float is a conversion. It performs some computation on 1 to come up with a Float value. Conversions are all library- or user-defined.

11.22.1 Casts

A cast \( v \text{ as } T \) re-imagines a value \( v \) of one type \( T_1 \) as being a value of another type \( T_2 \). The value itself does not change, nor is a new value computed. The only run-time computation that happens is to check that \( v \) is indeed a value of type \( T_2 \) (which, in many cases, is unnecessary), and auto-boxing (§9.2).

Casts to generic types can be unsound. The instantiations of the generic types have constraints, but the runtime does not preserve the representation of these types. See §4.5.5 for more details.

There are two forms of casts. **Upcasts** happen when \( T_1 \prec: T_2 \), that is, when a value is being cast to a more general type. Upcasts often don’t require any runtime computation at all, since, if \( T_1 \prec: T_2 \) and \( T_2 \text{ isref} \), every value of type \( T_1 \) is automatically one of type \( T_2 \). For example, "A String" as Any is a trivial upcast: every String can simply be used as a value of type Any because it is already represented as a heap-allocated object. Upcasts from structs to interface types however do require auto-boxing, such as 1 as Any.

**Downcasts** are casts which are not upcasts. Often they are recasting something from a more general to a more specific type, though casts that cross the type hierarchy laterally are also called downcasts.
val ob : Any = "a String" as Any; // upcast
val st : String = ob as String; // downcast
assert st == ob;

Example:

In the following example, Snack and Crunchy are unrelated interfaces: neither inherits from the other. Some objects are both; some are one but not the other. Casting from a Crunchy to a Snack requires confirming that the value being cast is indeed a Snack.

interface Snack {}
interface Crunchy {}
class Pretzel implements Snack, Crunchy{}
class Apricot implements Snack{}
class Gravel implements Crunchy{}
class Example{
def example(crunchy : Crunchy) {
    if (crunchy instanceof Snack) {
        val snack = crunchy as Snack;
    }
}
}

An upcast v as T2 requires no computation. A downcast v as T2 requires testing that v really is a value of type T2. In either case, the cast returns the value v; casts do not change value identity.

When evaluating E as T{c}, first the value of E is converted to type T (which may fail), and then the constraint {c} is checked (which may also fail).

- If T is a class, then the first half of the cast succeeds if the run-time value of E is an instance of class T, or of a subclass.
- If T is an interface, then the first half of the cast succeeds if the run-time value of E is an instance of a class or struct implementing T.
- If T is a struct type, then the first half of the cast succeeds if the run-time value of E is an instance of T.
- If T is a function type, then the first half of the cast succeeds if the run-time value of X is a function of that type, or an object or struct which implements it.

If the first half of the cast succeeds, the second half – the constraint {c} – must be checked. In general this will be done at runtime, though in special cases it can be checked at compile time. For example, n as Long{self != w} succeeds if \( n \neq w \) — even if \( w \) is a value read from input, and thus not determined at compile time.

The compiler may forbid casts that it knows cannot possibly work. If there is no way for the value of E to be of type T{c}, then E as T{c} can result in a static error, rather than a runtime error. For example, 1 as Long{self==2} may fail to compile,
because the compiler knows that 1, which has type `Long{self==1}`, cannot possibly be of type `Long{self==2}`.

If, for some reason, you need to write one of these forbidden casts, cast to `Any` first. `(1 as Any) as Long{self==2}` always returns false, but compiles.

### 11.22.2 Explicit Conversions

Explicit conversions are written with the same syntax as casts: `v as T2`. Explicit conversions transform a value of one type `T1` to an unrelated type `T2`. Unlike casts, conversions *do* execute code, and *may* (and generally do) return new values.

Explicit conversions do not arise spontaneously, as casts do. They may be programmed directly, using the `operator` syntax of §8.7.3 Implicit coercions can also be called explicitly as conversions. (The reverse is not true – explicit conversions cannot be used as implicit conversions.)

The numeric types in `x10.lang` have explicit conversions, as described in §11.23.1. These conversions enable `1 as Float` and the like.

**Example:** The following class has an explicit conversion from `Long` to `Knot`, and an implicit one from `String` to `Knot`. `a` uses the explicit conversion, `b` uses the implicit coercion, and `c` uses the implicit coercion explicitly.

```scala
class Knot(s:String){
  public def is(t:String):Boolean = s.equals(t);
  // explicit conversion
  public static operator (n:Long) as Knot = new Knot("knot-" + n);
  // implicit coercion
  public static operator (s:String):Knot = new Knot(s);
  // using them
  public static def example() {
    val a : Knot = 1 as Knot;
    val b : Knot = "frayed";
    val c : Knot = "three" as Knot;
    assert a.is("knot-1") && b.is("frayed") && c.is("three");
  }
}
```

### 11.22.3 Resolving Ambiguity

If `v as T` could either be a cast or an explicit coercion, X10 treats its as a cast. With the `VERBOSE` compiler flag, this is flagged as a warning.

**Example:** The `Person` class provides an explicit conversion from its subclass `Fop` to itself. However, since `Fop` is a subclass of `Person`, using the `as` operator invokes the upcast, rather than the explicit conversion. This is visible in the example because the
user-defined operator $f$ as Person returns new Person() (just like the asPerson method), while the upcast returns $f$ itself.

```scala
class Person {
  static operator (f:Fop) as Person = new Person();
  static def asPerson(f:Fop) = new Person();
  public static def example() {
    val f = new Fop();
    val cast = f as Person; // WARNING on this line
    assert cast == f;
    val meth = asPerson(f);
    assert meth !== f;
  }
}
class Fop extends Person {}
```

The definition of an explicit conversion in this case is of little value, since any use of it in the $f$ as Person syntax will invoke the upcast.

### 11.23 Coercions and conversions

A coercion does not change object identity: a coerced object may be explicitly coerced back to its original type through a cast. A conversion may change object identity if the type being converted to is not the same as the type converted from. X10 permits both user-defined coercions and conversions (§11.23.2).

#### 11.23.1 Coercions

\[
\text{CastExp} ::= \text{Primary} \mid \text{ExpName} \mid \text{CastExp as Type}
\]

**Subsumption coercion.** A value of a subtype may be implicitly coerced to any supertype.

**Example:** If Child <: Person and val rhys:Child, then rhys may be used in any context that expects a Person. For example,

```scala
class Example {
  def greet(Person) = "Hi!";
  def example(rhys: Child) {
    greet(rhys);
  }
}
```
Similarly, 2 (whose innate type is Long{self==2}) is usable in a context requiring a non-zero integer (Long{self != 0}).

Explicit Coercion (Casting with as) All classes and interfaces allow the use of the as operator for explicit type coercion. Any class or interface may be cast to any interface. Any interface may be cast to any class. Also, any interface can be cast to a struct that implements (directly or indirectly) that interface.

Example: In the following code, a Person is cast to Childlike. There is nothing in the class definition of Person that suggests that a Person can be Childlike. However, the Person in question, p, is actually a HappyChild—a subclass of Person—and is, in fact, Childlike.

Similarly, the Childlike value cl is cast to Happy. Though these two interfaces are unrelated, the value of cl is, in fact, Happy. And the Happy value hc is cast to the class Child, though there is no relationship between the two, but the actual value is a HappyChild, and thus the cast is correct at runtime.

Cyborg is a struct rather than a class. So, it cannot have sub structs, and all the interfaces of all Cyborgs are known: a Cyborg is Personable, but not Childlike or Happy. So, it is correct and meaningful to cast r to Personable. There is no way that a cast to Childlike could succeed, so r as Childlike is a static error.

```java
interface Personable {}
class Person implements Personable {}
interface Childlike extends Personable {}
class Child extends Person implements Childlike {}
struct Cyborg implements Personable {}
interface Happy {}
class HappyChild extends Child implements Happy {}
class Example {
  static def example() {
    var p : Person = new HappyChild();
    // class -> interface
    val cl : Childlike = p as Childlike;
    // interface -> interface
    val hc : Happy = cl as Happy;
    // interface -> class
    val ch : Child = hc as Child;
    var r : Cyborg = Cyborg();
    val rl : Personable = r as Personable;
    // ERROR: val no = r as Childlike;
  }
}
```

If the value coerced is not an instance of the target type, and no coercion operators that can convert it to that type are defined, a ClassCastException is thrown. Casting to a constrained type may require a run-time check that the constraint is satisfied.
It is a static error, rather than a ClassCastException, when the cast is statically determinable to be impossible.

**Effects of explicit numeric coercion** Coercing a number of one type to another type gives the best approximation of the number in the result type, or a suitable disaster value if no approximation is good enough.

- Casting a number to a *wider* numeric type is safe and effective, and can be done by an implicit conversion as well as an explicit coercion. For example, 4 as Long produces the Long value of 4.

- Casting a floating-point value to an integer value truncates the digits after the decimal point, thereby rounding the number towards zero. 54.321 as Int is 54n, and -54.321 as Int is -54n. If the floating-point value is too large to represent as that kind of integer, the coercion returns the largest or smallest value of that type instead: 1e10 as Int is Int.MAX_VALUE, viz. 2147483647.

- Casting a Double to a Float normally truncates binary digits: 0.12345678901234567890 as Float is approximately 0.12345679f. This can turn a nonzero Double into 0.0f, the zero of type Float: 1e-100 as Float is 0.0f. Since Doubles can be as large as about 1.79E308 and Floats can only be as large as about 3.4E38f, a large Double will be converted to the special Float value of Infinity: 1e100 as Float is Infinity.

- Integers are coerced to smaller integer types by truncating the high-order bits. If the value of the large integer fits into the smaller integer’s range, this gives the same number in the smaller type: 12 as Byte is the Byte-sized 12, -12 as Byte is -12. However, if the larger integer *doesn’t* fit in the smaller type, the numeric value and even the sign can change: 254 as Byte is the Bytesized -2y.

- Casting an unsigned integer type to a signed integer type of the same size (e.g., UInt to Int) preserves 2’s-complement bit pattern (e.g., UInt.MAX_VALUE as Int == -1n. Casting an unsigned integer type to a signed integer type of a different size is equivalent to first casting to an unsigned integer type of the target size, and then casting to a signed integer type.

- Casting a signed integer type to an unsigned one is similar.

**User-defined Coercions**

Users may define coercions from arbitrary types into the container type B, and coercions from B to arbitrary types, by providing static operator definitions for the as operator in the definition of B.

**Example:**
11.23.2 Conversions

Widening numeric conversion. A numeric type may be implicitly converted to a wider numeric type. In particular, an implicit conversion may be performed between a numeric type and a type to its right, below:

\[
\text{Byte} < \text{Short} < \text{Int} < \text{Long} < \text{Float} < \text{Double} \\
\text{UByte} < \text{UShort} < \text{UInt} < \text{ULong}
\]

Furthermore, an unsigned integer value may be implicitly coerced to a signed type large enough to hold any value of the type: \text{UByte} to \text{Short}, \text{UShort} to \text{Int}, \text{UInt} to \text{Long}.

There are no implicit conversions from signed to unsigned numbers, since they cannot treat negatives properly.

There are no implicit conversions in cases when overflow is possible. For example, there is no implicit conversion between \text{Int} and \text{UInt}. If it is necessary to convert between these types, use \text{n as Int} or \text{n as UInt}, generally with a test to ensure that the value will fit and code to handle the case in which it does not.

String conversion. Any value that is an operand of the binary + operator may be converted to \text{String} if the other operand is a \text{String}. A conversion to \text{String} is performed by invoking the \text{toString()} method.

User defined conversions. The user may define implicit conversion operators from type \text{A} to a container type \text{B} by specifying an operator in \text{B}'s definition of the form:

\[
\text{public static operator (r: A): T = ...}
\]

The return type \text{T} should be a subtype of \text{B}. The return type need not be specified explicitly; it will be computed in the usual fashion if it is not. However, it is good practice for the programmer to specify the return type for such operators explicitly. The return type can be more specific than simply \text{B}, for cases when there is more information available.

Example: The code for x10.lang.Point contains a conversion from a Rails of longs to Points of the same length:
public operator (r: Rail[Long]): Point(r.size) = make(r);

This conversion is used whenever a Rail of integers appears in a context that requires a Point, such as subscripting. Note that a requires a Point of rank 2 as a subscript, and that a two-element Rail (like [2, 4]) is converted to a Point(2).

val a = new Array[String](Region.make(2..3, 4..5), "hi!");
a([2,4]) = "converted!";

11.24 instanceof

X10 permits types to be used in an instanceof expression to determine whether an object is an instance of the given type:

\[
RelationalExp ::= ShiftExp \\
| HasZeroConstraint \\
| SubtypeConstraint \\
| RelationalExp < ShiftExp \\
| RelationalExp > ShiftExp \\
| RelationalExp <= ShiftExp \\
| RelationalExp >= ShiftExp \\
| RelationalExp instanceof Type
\]

In the above expression, Type is any type. At run time, the result of e instanceof T is true if the value of e is an instance of type T. Otherwise the result is false. This determination may involve checking that the constraint, if any, associated with the type is true for the given expression.

For example, 3 instanceof Long{self==x} is an overly-complicated way of saying 3==x.

However, it is a static error if e cannot possibly be an instance of C{c}; the compiler will reject 1 instanceof Long{self == 2} because 1 can never satisfy Long{self == 2}. Similarly, 1 instanceof String is a static error, rather than an expression always returning false.

If x instanceof T returns true for some value x and type T, then x as T will evaluate normally.

Limitation: X10 does not currently handle instanceof of generics in the way you might expect. For example, r instanceof Array[Long{self != 0}] does not test that every element of r is non-zero; instead, the compiler gives an unsound cast warning.
11.24.1 Nulls in Constraints in as and instanceof

Both as and instanceof expressions can throw NullPointerExceptions, if the constraints involve selecting fields or properties of variables which are bound to null. These operations give some guarantees for any type T, constraint c, and class SomeObj with an a field:

1. null instanceof T always returns false. It never throws an exception. It never returns true, not even in cases where null could be assigned to a variable of type T.

2. null can be assigned to a variable of type SomeObj{self.a==b}, or, more broadly, to a variable of a constrained object type whose constraint does not explicitly exclude null. This is the case even though null.a==b would throw a NullPointerException rather than evaluate to either true or false.

3. If x instanceof T returns true, then x as T is a cast rather than an explicit conversion, and will succeed and have static type T.

4. If the static type of x is T, then x instanceof T and x as T will do one of these:
   - Succeed, with x instanceof T returning true, and x as T being a cast and returning value of type T; or
   - Throw a NullPointerException.
   - If x==null, then x instanceof T will always return false, and x as T will either return a null of type T, or, if T has a constraint which tries to extract a field of x, will throw a NullPointerException.

5. If x instanceof SomeObj{self.a==b} is true, then x.a==b evaluates to true (rather than a null pointer exception). Indeed, in general, if x instanceof T{c} succeeds, then cc evaluates to true, where cc is c with suitable occurrences of self replaced by x.

11.25 Subtyping expressions

SubtypeConstraint ::= Type <: Type
                   | Type :> Type

The subtyping expression T₁ <: T₂ evaluates to true if T₁ is a subtype of T₂.
The expression T₁ :> T₂ evaluates to true if T₂ is a subtype of T₁.
The expression T₁ == T₂ evaluates to true if T₁ is a subtype of T₂ and if T₂ is a subtype of T₁.
Example: Subtyping expressions are particularly useful in giving constraints on
generic types. `x10.util.Ordered[T]` is an interface whose values can be compared
with values of type `T`. In particular, `T <: x10.util.Ordered[T]` is true if values of
type `T` can be compared to other values of type `T`. So, if we wish to define a generic
class `OrderedList[T]`, of lists whose elements are kept in the right order, we need
the elements to be ordered. This is phrased as a constraint on `T`:

```java
class OrderedList[T]{T <: x10.util.Ordered[T]} {
    // ...
}
```

11.26 Rail Constructors

```
Primary ::= [ ArgumentList? ]
```

X10 includes short syntactic forms for constructing Rails. Enclose some expressions
in brackets to put them in a Rail:

```java
val ints <: Rail[Long] = [1,3,7,21];
```

The expression `[e₁, ..., eₙ]` produces an `n`-element `Rail[T]`, where `T` is the com-
puted common supertype ([4.10] of the types of the expressions `eᵢ`.

Example: The type of `[0,1,2]` is `Rail[Long]`. The type of `[0]` is `Rail[Long{self==0}]`.

To make a `Rail[Long]` containing just a `0`, use `[0 as Long]`. The `as Long` masks
more detailed type information, such as the fact that `0` is zero.

Example: Occasionally one does actually need `Rail[Long{self==0}]`, or, say,
`Rail[Eel{self != null}]`, a rail of non-null Eels. For these cases, cast one or
more of the elements of the rail to the desired type, and the rail constructor will do the
right thing:

```java
val zero <: Rail[Long{self == 0}] = [0];
val non1 <: Rail[Long{self != 1}] = [0 as Long{self != 1}];
val eels <: Rail[Eel{self != null}] = [new Eel() as Eel{self != null},
                                     new Eel(), new Eel()];
```

11.27 Parenthesized Expressions

If `E` is any expression, `(E)` is an expression which, when evaluated, produces the same
result as `E`. 
Example: The main use of parentheses is to write complex expressions for which the standard precedence order of operations is not appropriate: \(1+2*3\) is 7, but \((1+2)*3\) is 9.

Similarly, but perhaps less familiarly, parentheses can disambiguate other expressions. In the following code, `funny.f` is a field-selection expression, and so `(funny.f)()` means “select the `f` field from `funny`, and evaluate it”. However, `funny.f()` means “evaluate the `f` method on object `funny`.”

```scala
class Funny {
  def f() = 1;
  val f = () => 2;
  static def example() {
    val funny = new Funny();
    assert funny.f() == 1;
    assert (funny.f)() == 2;
  }
}
```

Note that this does not mean that \(E\) and \((E)\) are identical in all respects; for example, if \(i\) is a `Long` variable, \(i++\) increments \(i\), but \((i)++\) is not allowed. ++ is an assignment; it operates on variables, not merely values, and \((i)\) is simply an expression whose value is the same as that of \(i\).
12 Statements

This chapter describes the statements in the sequential core of X10. Statements involving concurrency and distribution are described in §14.

12.1 Empty statement

The empty statement ; does nothing.

Example: Sometimes, the syntax of X10 requires a statement in some position, but you do not actually want to do any computation there. The following code searches the rail a for the value v, assumed to appear somewhere in a, and returns the index at which it was found. There is no computation to do in the loop body, so we use an empty statement there.

```scala
static def search[T](a: Rail[T], v: T):Long {
  var i : Long;
  for(i = 0L; a(i) != v; i++)
    ;
  return i;
}
```
12.2 Local variable declaration

\[
\text{LocVarDecln ::= } \text{Mods}^? \VarKeyword \text{VariableDeclrs} \quad (20.110) \\
\text{ | } \text{Mods}^? \text{VarDeclsWType} \\
\text{ | } \text{Mods}^? \VarKeyword \text{ FormalDeclrs} \\
\text{LocVarDeclnStmt ::= } \text{LocVarDecln ;} \quad (20.111) \\
\text{VarDeclsWType ::= } \text{VarDeclWType} \quad (20.201) \\
\text{ | } \text{VarDeclsWType , VarDeclWType} \\
\text{VariableDeclrs ::= } \text{VariableDeclr} \quad (20.204) \\
\text{ | } \text{VariableDeclrs , VariableDeclr} \\
\text{VariableInitializer ::= } \text{Exp} \quad (20.205) \\
\text{FormalDeclrs ::= } \text{FormalDeclr} \quad (20.78) \\
\text{ | } \text{FormalDeclrs , FormalDeclr} \\
\]

Short-lived variables are introduced by local variables declarations, as described in §12.2. Local variables may be declared only within a block statement (§12.3). The scope of a local variable declaration is the subsequent statements in the block.

```
if (a > 1) {
  val b = a/2;
  var c : Long = 0;
  // b and c are defined here
}
// b and c are not defined here.
```

Variables declared in such statements shadow variables of the same name declared elsewhere. A local variable of a given name, say \( x \), cannot shadow another local variable or parameter named \( x \) unless there is an intervening method, constructor, initializer, or closure declaration.

**Example:** The following code illustrates both legal and illegal uses of shadowing. Note that a shadowed field name \( x \) can still be accessed as \texttt{this.x}.

```
class Shadow{
  var x : Long;
  def this(x:Long) {
    // Parameter can shadow field
    this.x = x;
  }
  def example(y:Long) {
    val x = "shadows a field";
    // ERROR: val y = "shadows a param";
    val z = "local";
    for (a in [1,2,3]) {
      // ERROR: val x = "can’t shadow local var";
    }
    async {
```

12.3. BLOCK STATEMENT

// ERROR: val x = "can't shadow through async";
}
val f = () => {
    val x = "can shadow through closure";
    x
};
class Local {
    val f = at(here) { val x = "can here"; x }
    def this() { val x = "can here, too"; }
}
}

Example: Note that recursive definitions of local variables is not allowed. There are few useful recursive declarations of objects and structs; x, in the following example, has no meaningful definition. Recursive declarations of local functions is forbidden, even though (like f below) there are meaningful uses of it.

val x : Long = x + 1; // ERROR: recursive local declaration
val f : (Long)=>Long
    = (n:Long) => (n <= 2) ? 1 : f(n-1) + f(n-2);
    // ERROR: recursive local declaration

12.3 Block statement

Block ::= { BlockStmts }  
BlockStmts ::= BlockInteriorStmt  
| BlockStmts BlockInteriorStmt  
BlockInteriorStmt ::= LocVarDeclnStmt  
| ClassDecln  
| StructDecln  
|TypeDefDecln  
|Stmt

A block statement consists of a sequence of statements delimited by “{” and “}”. When a block is evaluated, the statements inside of it are evaluated in order. Blocks are useful for putting several statements in a place where X10 asks for a single one, such as the consequent of an if, and for limiting the scope of local variables.

if (b) {
    // This is a block
    val v = 1;
    S1(v);
    S2(v);
}
12.4 Expression statement

Any expression may be used as a statement.

\[
\begin{align*}
\text{ExpStmt} & \ ::= \text{StmtExp} \\
\text{StmtExp} & \ ::= \text{Assignment} \quad (20.152) \\
& \quad | \text{PreIncrementExp} \\
& \quad | \text{PreDecrementExp} \\
& \quad | \text{PostIncrementExp} \\
& \quad | \text{PostDecrementExp} \\
& \quad | \text{MethodInvo} \\
& \quad | \text{ObCreationExp}
\end{align*}
\]

The expression statement evaluates an expression. The value of the expression is not used. Side effects of the expression occur, and may produce results used by following statements. Indeed, statement expressions which terminate without side effects cannot have any visible effect on the results of the computation.

Example:

```java
class StmtEx {
    def this() {
        x10.io.Console.OUT.println("New StmtEx made");
    }
    static def call() {
        x10.io.Console.OUT.println("call!");
    }
    def example() {
        var a : Long = 0;
        a = 1; // assignment
        new StmtEx(); // allocation
        call(); // call
    }
}
```

12.5 Labeled statement

\[
\text{LabeledStatement} \ ::= \ Id : \text{Statement}
\]

Statements may be labeled. The label may be used to describe the target of a break statement appearing within a substatement (which, when executed, ends the labeled statement), or, in the case of a loop, a continue as well (which, when executed, proceeds to the next iteration of the loop). The scope of a label is the statement labeled.

Example: The label on the outer for statement allows continue and break statements to continue or break it. Without the label, continue or break would only continue or break the inner for loop.
In particular, a block statement may be labeled: \( L: \{ S \} \). This allows the use of `break L` within `S` to leave `S`, which can, if carefully used, avoid deeply-nested if's.

Example:

```plaintext
multiphase: {
    if (!exists(filename)) break multiphase;
    phase1(filename);
    if (!suitable_for_phase_2(filename)) break multiphase;
    phase2(filename);
    if (!suitable_for_phase_3(filename)) break multiphase;
    phase3(filename);
}
// Now the file has been phased as much as possible
```

**Limitation:** Blocks cannot currently be labeled.

### 12.6 Break statement

**BreakStmt** \( := \) `break Id` ;

An unlabeled break statement exits the currently enclosing loop or switch statement. A labeled break statement exits the enclosing statement with the given label. It is illegal to break out of a statement not defined in the current method, constructor, initializer, or closure. `break` is only allowed in sequential code.

**Example:** The following code searches for an element of a C-style two-dimensional array and breaks out of the loop when it is found:

```plaintext
var found: Boolean = false;
outer: for (i in a.range) 
    for (j in a(i).range)
        if (a(i)(j) == v) {
            found = true;
            break outer;
        }
```
12.7 Continue statement

\[ \text{ContinueStmt} ::= \text{continue Id}^? ; \]  

An unlabeled `continue` skips the rest of the current iteration of the innermost enclosing loop, and proceeds on to the next. A labeled `continue` does the same to the enclosing loop with that label. It is illegal to continue a loop not defined in the current method, constructor, initializer, or closure. `continue` is only allowed in sequential code.

12.8 If statement

\[ \text{IfThenStmt} ::= \text{if ( Exp ) Stmt} \]  
\[ \text{IfThenElseStmt} ::= \text{if ( Exp ) Stmt else Stmt} \]

An if statement comes in two forms: with and without an else clause.

The if-then statement evaluates a condition expression, which must be of type `Boolean`. If the condition is `true`, it evaluates the then-clause. If the condition is `false`, the if-then statement completes normally.

The if-then-else statement evaluates a `Boolean` expression and evaluates the then-clause if the condition is `true`; otherwise, the `else`-clause is evaluated.

As is traditional in languages derived from Algol, the if-statement is syntactically ambiguous. That is,

\[ \text{if (B1) if (B2) S1 else S2} \]

could be intended to mean either

\[ \text{if (B1) \{ if (B2) S1 else S2 \}} \]

or

\[ \text{if (B1) \{if (B2) S1\} else S2} \]

X10, as is traditional, attaches an `else` clause to the most recent `if` that doesn’t have one. This example is interpreted as `if (B1) \{ if (B2) S1 else S2 \}`.
12.9 Switch statement

A switch statement evaluates an index expression and then branches to a case whose value is equal to the value of the index expression. If no such case exists, the switch branches to the default case, if any.

Statements in each case branch are evaluated in sequence. At the end of the branch, normal control-flow falls through to the next case, if any. To prevent fall-through, a case branch may be exited using a break statement.

The index expression must be of type Int. Case labels must be of type Int, Byte, or Short, and must be compile-time constants. Case labels cannot be duplicated within the switch statement.

Example: In this switch, case 1 falls through to case 2. The other cases are separated by breaks.

```java
switch (i) {
    case 1n: println("one, and ");
    case 2n: println("two");
        break;
    case 3n: println("three");
        break;
    default: println("Something else");
        break;
}
```

12.10 While statement

A while statement evaluates a Boolean-valued condition and executes a loop body if true. If the loop body completes normally (either by reaching the end or via a continue statement with the loop header as target), the condition is reevaluated and the loop repeats if true. If the condition is false, the loop exits.
Example: A loop to execute the process in the Collatz conjecture (a.k.a. 3n+1 problem, Ulam conjecture, Kakutani’s problem, Thwaites conjecture, Hasse’s algorithm, and Syracuse problem) can be written as follows:

```java
while (n > 1) {
    n = (n % 2 == 1) ? 3*n+1 : n/2;
}
```

### 12.11 Do–while statement

A do–while statement executes the loop body, and then evaluates a Boolean-valued condition expression. If true, the loop repeats. Otherwise, the loop exits.

### 12.12 For statement

```latex
ForStmt ::= BasicForStmt | EnhancedForStmt
BasicForStmt ::= for ( ForInit? ; Exp? ; ForUpdate? ) Stmt
ForInit ::= StmtExpList | LocVarDecln
ForUpdate ::= StmtExpList
StmtExpList ::= StmtExp | StmtExpList , StmtExp
EnhancedForStmt ::= for ( LoopIndex in Exp ) Stmt | for ( Exp ) Stmt
```

For statements provide bounded iteration, such as looping over a list. It has two forms: a basic form allowing near-arbitrary iteration, \textit{a la} C, and an enhanced form designed to iterate over a collection.

A basic for statement provides for arbitrary iteration in a somewhat more organized fashion than a while. The loop for(init; test; step)body is similar to:

```java
{
    init;
    while(test) {
        body;
        step;
    }
}
```
except that continue statements which continue the for loop will perform the step, which, in the while loop, they will not do.

init is performed before the loop, and is traditionally used to declare and/or initialize the loop variables. It may be a single variable binding statement, such as `var i:Long = 0` or `var i:Long=0, j:Long=100`. (Note that a single variable binding statement may bind multiple variables.) Variables introduced by init may appear anywhere in the for statement, but not outside of it. Or, it may be a sequence of expression statements, such as `i=0, j=100`, operating on already-defined variables. If omitted, init does nothing.

test is a Boolean-valued expression; an iteration of the loop will only proceed if test is true at the beginning of the loop, after init on the first iteration or after step on later ones. If omitted, test defaults to true, giving a loop that will run until stopped by some other means such as break, return, or throw.

step is performed after the loop body, between one iteration and the next. It traditionally updates the loop variables from one iteration to the next: e.g., `i++` and `i++, j--`. If omitted, step does nothing.

body is a statement, often a code block, which is performed whenever test is true. If omitted, body does nothing.

An enhanced for statement is used to iterate over a collection, or other structure designed to support iteration by implementing the interface `Iterable[T]`. The loop variable must be of type T, or destructurable from a value of type T (§5). Each iteration of the loop binds the iteration variable to another element of the collection. The loop `for(x in c)S` behaves like:

```scala
val iterator: Iterator[T] = c.iterator();
while (iterator.hasNext()) {
  val x : T = iterator.next();
  S();
}
```

A number of library classes implement `Iterable`, and thus can be iterated over. For example, iterating over a Rail iterates the elements stored in the rail.

The type of the loop variable may be supplied as `x <: T`. In this case the iterable c must have type `Iterable[U]` for some `U <: T`, and x will be given the type U.

**Example:** This loop adds up the elements of a `List[Long]`. Note that iterating over a list yields the elements of the list, as specified in the `List API`.

```scala
static def sum(a:x10.util.List[Long]):Long {
  var s : Long = 0;
  for(x in a) s += x;
  return s;
}
```

The following code sums the elements of an integer rail.
static def sum(a: Rail[Long]): Long {
    var s : Long = 0;
    for(v in a) s += v;
    return s;
}

Iteration over a LongRange is quite common. This allows looping while varying a long index:

    var sum : Long = 0;
    for(i in 1..10) sum += i;
    assert sum == 55;

Iteration variables have the for statement as scope. They shadow other variables of the same names.

12.13 Return statement

ReturnStmt ::= return Exp? ;

Methods and closures may return values using a return statement. void methods must return without a value; other methods must return a value of the return type.

Example: The following code illustrates returning values from a closure and a method. The return inside of closure returns from closure, not from method.

    def method(x:Long) {
        val closure = (y:Long) => {return x+y;};
        val res = closure(0);
        assert res == x;
        return res == x;
    }

12.14 Assert statement

AssertStmt ::= assert Exp ;
             | assert Exp : Exp ;

The statement assert E checks that the Boolean expression E evaluates to true, and, if not, throws an x10.lang.Error exception. The annotated assertion statement assert E : F; checks E, and, if it is false, throws an x10.lang.Error exception with F’s value attached to it.

Example: The following code compiles properly.
class Example {
    public static def main(argv:Rail[String]) {
        val a = 1;
        assert a != 1 : "Changed my mind about a.";
    }
}

However, when run, it prints a stack trace starting with

### 12.15 Exceptions in X10

X10 programs can throw exceptions to indicate unusual or problematic situations; this is abrupt termination. Exceptions, as data values, are instances of `x10.lang.CheckedThrowable` or its subclasses. Note that for ease of implementation X10 does not permit subclasses of `x10.lang.CheckedThrowable` to be generic, that is, take type parameters.

Exceptions may be thrown intentionally with the `throw` statement. Many primitives and library functions throw exceptions if they encounter problems; e.g., dividing by zero throws an instance of `x10.lang.ArithmeticException`.

When an exception is thrown, dynamically enclosing `try`-catch blocks in the same activity can attempt to handle it. If the throwing statement is inside some `try` clause, and some matching `catch` clause catches that type of exception, the corresponding `catch` body will be executed, and the process of throwing is finished. If no statically-enclosing `try`-catch block can handle the exception, the current method call returns (abnormally), throwing the same exception from the point at which the method was called.

This process continues until the exception is handled or there are no more calling methods in the activity. In the latter case, the activity will terminate abnormally, and the exception will propagate to the activity's root; see 14.1 for details.

X10 supports both checked and unchecked exceptions. Methods are obligated to declare via a `throws` clause any checked exceptions that they might throw. However, in X10, the class library design favors unchecked exceptions: virtually all exceptions in the standard library are unchecked. Checked exceptions are defined to be any subclass of `x10.lang.CheckedThrowable` that are not also subclasses of either `x10.lang.Exception` or `x10.lang.Error`. All of the concrete exception classes in the X10 standard library are subclasses of either `Exception` or `Error`.

### 12.16 Throw statement

\[
\text{ThrowStmt} \ ::= \ \text{throw} \ \text{Exp} ;
\]
throw E throws an exception whose value is E, which must be an instance of a subtype of x10.lang.CHECKEDTHROWABLE.

**Example:** The following code checks if an index is in range and throws an exception if not.

```java
if (i < 0 || i >= x.size)
    throw new MyIndexOutOfBoundsException();
```

### 12.17 Try–catch statement

```plaintext
try Block Catches
| try Block Catches? Finally
Catches ::= CatchClause
| Catches CatchClause
CatchClause ::= catch (Formal) Block
Finally ::= finally Block
```

Exceptions are handled with a try statement. A try statement consists of a try block, zero or more catch blocks, and an optional finally block.

First, the try block is evaluated. If the block throws an exception, control transfers to the first matching catch block, if any. A catch matches if the value of the exception thrown is a subclass of the catch block’s formal parameter type.

The finally block, if present, is evaluated on all normal and exceptional control-flow paths from the try block. If the try block completes normally or via a return, a break, or a continue statement, the finally block is evaluated, and then control resumes at the statement following the try statement, at the branch target, or at the caller as appropriate. If the try block completes exceptionally, the finally block is evaluated after the matching catch block, if any, and when and if the finally block finishes normally, the exception is rethrown.

The parameter of a catch block has the block as scope. It shadows other variables of the same name.

**Example:** The example() method below executes without any assertion errors

```java
class Example {
    class ThisExn extends Exception {}
    class ThatExn extends Exception {}
    var didFinally : Boolean = false;
    def example(b:Boolean) {
        try {
            throw b ? new ThatExn() : new ThisExn();
        }
        catch(ThatExn) {return true;}
    }
```
catch(ThisExn) {return false;}
finally {
    this.didFinally = true;
}
}
static def doExample() {
    val e = new Example();
    assert e.example(true);
    assert e.didFinally == true;
}

Limitation: Constraints on exception types in catch blocks are not currently supported.

12.18 Assert

The assert statement assert B; checks that the Boolean expression B evaluates to true. If so, computation proceeds. If not, it throws x10.lang.AssertionError.

The extended form assert B:A; is similar, but provides more debugging information. The value of the expression A is available as part of the AssertionError, e.g., to be printed on the console.

Example: assert is useful for confirming properties that you believe to be true and wish to rely on. In particular, well-chosen asserts make a program robust in the face of code changes and unexpected uses of methods. For example, the following method compute percent differences, but asserts that it is not dividing by zero. If the mean is zero, it throws an exception, including the values of the numbers as potentially useful debugging information.

static def percentDiff(x:Double, y:Double) {
    val diff = x-y;
    val mean = (x+y)/2;
    assert mean != 0.0 : [x,y];
    return Math.abs(100 * (diff / mean));
}

At times it may be considered important not to check assert statements; e.g., if the test is expensive and the code is sufficiently well-tested. The -noassert command line option causes the compiler to ignore all assert statements.
13 Places

An X10 place is a repository for data and activities, corresponding loosely to a process or a processor. Places induce a concept of “local”. The activities running in a place may access data items located at that place with the efficiency of on-chip access. Accesses to remote places may take orders of magnitude longer. X10’s system of places is designed to make this obvious. Programmers are aware of the places of their data, and know when they are incurring communication costs, but the actual operation to do so is easy. It’s not hard to use non-local data; it’s simply hard to do so accidentally.

The set of places available to a computation is determined at the time that the program is started, and remains fixed through the run of the program. See the README documentation on how to set command line and configuration options to set the number of places.

Places are first-class values in X10, as instances x10.lang.Place. Place provides a number of useful ways to query places, such as Place.places(), which returns a PlaceGroup of the places available to the current run of the program.

Objects and structs are created in a single place – the place that the constructor call was running in. They cannot change places. They can be copied to other places, and the special library struct GlobalRef allows values at one place to point to values at another.

13.1 The Structure of Places

Places are numbered starting at 0; the number is stored in the field pl.id. The method Place.numPlaces() returns the number of Places in the current execution of the program. The program starts by executing a main method at Place.FIRST_PLACE, which is Place.places()(0); see §14.4

13.2 here

The variable here is always bound to the place at which the current computation is running, in the same way that this is always bound to the instance of the current
class (for non-static code), or \texttt{self} is bound to the instance of the type currently being constrained. \texttt{here} may denote different places in the same method body or even the same expression, due to place-shifting operations.

This is not unusual for automatic variables: \texttt{self} denotes two different values (one \texttt{List}, one \texttt{Long}) when one describes a non-null list of non-zero numbers as \texttt{List[Long\{self!=0\}\{self!=null\}].}

In the following code, \texttt{here} has one value at \texttt{h0}, and a different one at \texttt{h1} (unless there is only one place).

```scala
val h0 = here;
val world = Place.places();
at (world.next(here)) {
  val h1 = here;
  assert (h0 != h1);
}
```

(Similar examples show that \texttt{self} and \texttt{this} have the same behavior: \texttt{self} can be shadowed by constrained types appearing inside of type constraints, and \texttt{this} by inner classes.)

The following example looks through a list of references to \texttt{Things}. It finds those references to things that are \texttt{here}, and deals with them.

```scala
public static def deal(things: List[GlobalRef[Thing]]) {
  for(gr in things) {
    if (gr.home == here) {
      val grHere =
        gr as GlobalRef[Thing]\{gr.home == here\};
      val thing <: Thing = grHere();
      dealWith(thing);
    }
  }
}
```

### 13.3 \texttt{at}: Place Changing

An activity may change place synchronously using the \texttt{at} statement or \texttt{at} expression. Like any distributed operation, it is potentially expensive, as it requires, at a minimum, two messages and the copying of all data used in the operation, and must be used with care – but it provides the basis for distributed programming in \texttt{X10}.

\[
\begin{align*}
\text{AtStmt} & ::= \text{at} \ (\ \text{Exp} \ ) \ \text{Stmt} \\
\text{AtExp} & ::= \text{at} \ (\ \text{Exp} \ ) \ \text{ClosureBody}
\end{align*}
\]

The \texttt{PlaceExp} must be an expression of type \texttt{Place} or some subtype. For programming convenience, if \texttt{PlaceExp} is of type \texttt{GlobalRef[T]} then the \texttt{home} property of \texttt{GlobalRef} is used as the value of \texttt{PlaceExp}. 

An activity may also spawn an asynchronous remote child activity. For optimal performance, it is desirable for the spawning activity to continue executing locally without waiting for the message creating the remote child activity to arrive at the destination place. X10 supports this “fire-and-forget” style of remote activity creation by special handling of the combination of \( \texttt{at (P) async S} \). In particular, any exceptions raised during deserialization (\[13.3.2\]) at the remote place will be reported asynchronously (as if they occurred after the remote activity \( \texttt{async S} \) was spawned).

**Example:** The following example creates a rail a located here, and copies it to another place. a in the second place refers to the copy. The copy is modified and examined. After the at finishes, the original is also examined, and (since only the copy, not the original, was modified) is observed to be unchanged.

```scala
val a = [1,2,3];
val world = Place.places();
at(world.next(here)) {
    a(1) = 4;
    assert a(0)==1 && a(1)==4 && a(2)==3;
}
assert a(0)==1 && a(1)==2 && a(2)==3;
```

### 13.3.1 Copying Values

An activity executing \( \texttt{at(q)S} \) at a place p evaluates q at place p, which should be a Place. It then moves to place q to execute S. The values variables that S refers to are copied (\[13.3.2\]) to q, and bound to the variables of the same name. If the at is inside of an instance method and S uses this, this is copied as well. Note that a field reference this.fld or a method call this.meth() will cause this to be copied — as will their abbreviated forms fld and meth(), despite the lack of a visible this.

Note that the value obtained by evaluating q is not necessarily distinct from p (e.g., q may be here). This does not alter the behavior of \( \texttt{at(here)S} \) will copy all the values mentioned in S, even though there is no actual change of place, and even though the original values already exist there.

On normal termination of S control returns to p and execution is continued with the statement following \( \texttt{at (q) S} \). If S terminates abruptly with exception E, E is serialized into a buffer, the buffer is communicated to p where it is deserialized into an exception E1 and at \( \texttt{(p) S} \) throws E1.

Since \( \texttt{at(p) S} \) is a synchronous construct, usual control-flow constructs such as break, continue, return and throw are permitted in S. All concurrency related constructs – async, finish, atomic, when are also permitted.

The at-expression \( \texttt{at(p)E} \) is similar, except that, in the case of normal termination of E, the value that E produces is serialized into a buffer, transported to the starting place, and deserialized, and the value of the at-expression is the result of deserialization.

**Limitation:** X10 does not currently allow break, continue, or return to exit from an at.
13.3.2 How at Copies Values

The values mentioned in $S$ are copied to place $p$ by $\text{at}(p)S$ as follows.

First, the original-expressions are evaluated to give a vector of X10 values. Consider the graph of all values reachable from these values (except for transient fields (§13.3.5) GlobalRefs (§13.3.6), also custom serialization (§13.3.2 may alter this behavior)).

Second this graph is serialized into a buffer and transmitted to place $q$. Third, the vector of X10 values is re-created at $q$ by deserializing the buffer at $q$. Fourth, $S$ is executed at $q$, in an environment in which each variable $v$ declared in $F$ refers to the corresponding deserialized value.

Note that since values accessed across an at boundary are copied, the programmer may wish to adopt the discipline that either variables accessed across an at boundary contain only structs or stateless objects, or the methods invoked on them do not access any mutable state on the objects. Otherwise the programmer has to ensure that side effects are made to the correct copy of the object. For this the struct `x10.lang.GlobalRef[T]` is often useful.

Serialization and deserialization.

The X10 runtime provides a default mechanism for serializing/deserializing an object graph with a given set of roots. This mechanism may be overridden by the programmer on a per class or struct basis as described in the API documentation for `x10.io.CustomSerialization`. The default mechanism performs a deep copy of the object graph (that is, it copies the object or struct and, recursively, the values contained in its fields), but does not traverse or copy transient fields. Transient fields are omitted from the serialized data. On deserialization, transient fields are initialized with their default values (§4.7). The types of transient fields must therefore have default values.

The default serialization/deserialization mechanism will not (modulo error conditions like `OutOfMemoryError`) throw any exceptions. However, user code running during serialization/deserialization via `CustomSerialization` may raise exceptions. These exceptions are handled like any other exception raised during the execution of an X10 activity. However, due to the special treatment of $\text{at} \ (p)$ async $S$ (§13.3) any exception raised during deserialization will be handled as if it was raised by async $S$, not by the at statement itself.

A struct $s$ of type `x10.lang.GlobalRef[T]` is serialized as a unique global reference to its contained object $o$ (of type $T$). Please see the documentation of `x10.lang.GlobalRef[T]` for more details.

13.3.3 at and Activities

$\text{at}(p)S$ does not start a new activity. It should be thought of as transporting the current activity to $p$, running $S$ there, and then transporting it back. async is the only construct
in the language that starts a new activity. In different contexts, each one of the following combination of async and at makes sense: (1) at(p) async S and, (2) async at(p) S. In the first case, the expression p is evaluated synchronously by the current activity and then a single remote async is spawned. In the second case, p is semantically required to be evaluated asynchronously with the parent async as it is contained in the body of an async. Then the evaluation of S is transported to the new place. In most cases, the first form (at(p) async S) is preferred to second one (async at(p) S), since it enables a more efficient runtime implementation (it avoids the spawning a local async solely to evaluate p).

Since at(p) S does not start a new activity, S may contain constructs which only make sense within a single activity. For example,

```scala
for(x in globalRefsToThings)
  if (at(x.home) x().isNice())
    return x();
```

returns the first nice thing in a collection. If we had used async at(x.home), this would not be allowed; you can't return from an async.

**Limitation:** X10 does not currently allow break, continue, or return to exit from an at.

### 13.3.4 Copying from at

at(p)S copies data required in S, and sends it to place p, before executing S there. The only things that are not copied are values only reachable through GlobalRefs and transient fields, and data omitted by custom serialization.

**Example:**

```scala
val c = new Cell[Long](9); // (1)
at (here) {
  assert(c() == 9); // (3)
c.set(8);  // (4)
  assert(c() == 8); // (5)
}
assert(c() == 9); // (6)
```

*The at statement copies the Cell and its contents. After (1), c is a Cell containing 9; call that cell c1 At (2), that cell is copied, resulting in another cell c2 whose contents are also 9, as tested at (3). (Note that the copying behavior of at happens even when the destination place is the same as the starting place—even with at(here).) At (4), the contents of c2 are changed to 8, as confirmed at (5); the contents of c1 are of course untouched. Finally, at (c), outside the scope of the at started at line (2), c refers to its original value c1 rather than the copy c2.*

The at statement induces a *deep copy*. Not only does it copy the values of variables, it copies values that they refer to through zero or more levels of reference. Structures are
preserved as well: if two fields \( x.f \) and \( x.g \) refer to the same object \( o_1 \) in the original, then \( x.f \) and \( x.g \) will both refer to the same object \( o_2 \) in the copy.

**Example:** In the following variation of the preceding example, \( a \)'s original value \( a_1 \) is a trail with two references to the same \( \text{Cell[Long]} \) \( c_1 \). The fact that \( a_1(0) \) and \( a_1(1) \) are both identical to \( c_1 \) is demonstrated in (A)-(C), as \( a_1(0) \) is modified and \( a_1(1) \) is observed to change. In (D)-(F), the copy \( a_2 \) is tested in the same way, showing that \( a_2(0) \) and \( a_2(1) \) both refer to the same \( \text{Cell[Long]} \) \( c_2 \). However, the test at (G) shows that \( c_2 \) is a different cell from \( c_1 \), because changes to \( c_2 \) did not propagate to \( c_1 \).

```scala
val c = new Cell[Long](5);
val a : Rail[Cell[Long]] = [c, c as Cell[Long]];
assert(a(0)() == 5 && a(1)() == 5);  // (A)
c.set(6);                          // (B)
assert(a(0)() == 6 && a(1)() == 6); // (C)
at(here) {
  assert(a(0)() == 6 && a(1)() == 6); // (D)
c.set(7);                           // (E)
  assert(a(0)() == 7 && a(1)() == 7); // (F)
}
assert(a(0)() == 6 && a(1)() == 6);  // (G)
```

### 13.3.5 Copying and Transient Fields

Recall that fields of classes and structs marked `transient` are not copied by `at`. Instead, they are set to the default values for their types. Types that do not have default values cannot be used in `transient` fields.

**Example:** Every `Trans` object has an \( a \)-field equal to \( 1 \). However, despite the initializer on the \( b \) field, it is not the case that every `Trans` has \( b==2 \). Since \( b \) is transient, when the `Trans` value this is copied at `at(here){...} in example()`, its \( b \) field is not copied, and the default value for an \( \text{Long} \), 0, is used instead. Note that we could not make a transient field `c : Long{c != 0}` since the type has no default value, and copying would in fact set it to zero.

```scala
class Trans {
  val a : Long = 1;
  transient val b : Long = 2;
  //ERROR: transient val c : Long{c != 0} = 3;
  def example() {
    assert(a == 1 && b == 2);
    at(here) {
      assert(a == 1 && b == 0);
    }
  }
}
```
13.3.6 Copying and GlobalRef

A GlobalRef[T] (say g) contains a reference to a value v of type T, in a form which can be transmitted, and a Place g.home indicating where the value lives. When a GlobalRef is serialized an opaque, globally unique handle to v is created.

Example: The following example does not copy the value huge. However, huge would have been copied if it had been put into a Cell, or simply used directly.

```scala
val huge = "A potentially big thing";
val href = GlobalRef(huge);
at (here) {
  use(href);
}
```

Values protected in GlobalRefs can be retrieved by the application operation g(). g() is guarded; it can only be called when g.home == here. If you want to do anything other than pass a global reference around or compare two of them for equality, you need to placeshift back to the home place of the reference, often with at(g.home).

Example: The following program, for reasons best known to the programmer, modifies the command-line argument array.

```scala
public static def main(argv:Rail[String]) {
  val argref = GlobalRef[Rail[String]](argv);
  val world = Place.places();
  at(world.next(here))
    use(argref);
}
static def use(argref : GlobalRef[Rail[String]]) {
  at(argref) {
    val argv = argref();
    argv(0) = "Hi!";
  }
}
```

There is an implicit coercion from GlobalRef[T] to Place, so at(argref)S goes to argref.home.

13.3.7 Warnings about at

There are two dangers involved with at:

- Careless use of at can result in copying and transmission of very large data structures. In particular, it is very easy to capture this – a field reference will do it – and accidentally copy everything that this refers to, which can be very large. A disciplined use of copy specifiers to make explicit just what gets copied can ameliorate this issue.
• As seen in the examples above, a local variable reference x may refer to different objects in different nested at scopes. The programmer must either ensure that a variable accessed across an at boundary has no mutable state or be prepared to reason about which copy gets modified. A disciplined use of copy specifiers to give different names to variables can ameliorate this concern.
# 14 Activities

An activity is a statement being executed, independently, with its own local variables; it may be thought of as a very light-weight thread. An X10 computation may have many concurrent activities executing at any give time. All X10 code runs as part of an activity; when an X10 program is started, the main method is invoked in an activity, called the root activity.

Activities progress by executing control structures. For example, when(x==0); blocks the current activity until some other activity sets x to zero. However, activities determine the loca at which they may be blocked and resumed, using when and similar constructs. There are no means by which one activity can arbitrarily interrupt, block, kill or resume another.

An activity may be running, blocked on some condition or terminated. An activity terminates when it has no more statements to execute; it terminates normally (abruptly) if the last statement it executes terminates normally (abruptly) (§14.1).

Activities can be long-running, and may access a lot of data. In particular they can call recursive methods (and therefore have runtime stacks). However, activities can also perform very few actions, such as incrementing some variables.

An activity may asynchronously and in parallel launch activities. Every activity except the initial main activity is spawned by another. Thus, at any instant, the activities in a program form a tree.

X10 uses this tree in crucial ways. First is the distinction between local termination and global termination of a statement. The execution of a statement by an activity is said to terminate locally when the activity has finished all its computation. (For instance the creation of an asynchronous activity terminates locally when the activity has been created.) It is said to terminate globally when it has terminated locally and all activities that it may have spawned have, recursively, terminated globally. For example, consider:

```pseudocode
async {s1();}
async {s2();}
```

The primary activity spawns two child activities and then terminates locally, very quickly. The child activities may take arbitrary amounts of time to terminate (and may spawn grandchildren). When s1(), s2(), and all their descendants terminate locally, then the primary activity terminates globally.
14.1. THE X10 ROOTED EXCEPTION MODEL

The program as a whole terminates when the root activity terminates globally. In particular, X10 does not permit the creation of daemon threads—threads that outlive the lifetime of the root activity. We say that an X10 computation is rooted (§14.4).

Future Extensions. We may permit the initial activity to be a daemon activity to permit reactive computations, such as webservers, that may not terminate.

14.1 The X10 rooted exception model

The rooted nature of X10 computations permits the definition of a rooted exception model. In multi-threaded programming languages there is a natural parent-child relationship between a thread and a thread that it spawns. Typically the parent thread continues execution in parallel with the child thread. Therefore the parent thread cannot serve to catch any exceptions thrown by the child thread.

The presence of a root activity and the concept of global termination permits X10 to adopt a more powerful exception model. In any state of the computation, say that an activity $A$ is a root of an activity $B$ if $A$ is an ancestor of $B$ and $A$ is blocked at a statement (such as the finish statement §14.3) awaiting the termination of $B$ (and possibly other activities). For every X10 computation, the root-of relation is guaranteed to be a tree. The root of the tree is the root activity of the entire computation. If $A$ is the nearest root of $B$, the path from $A$ to $B$ is called the activation path for the activity.\(^1\)

We may now state the exception model for X10. An uncaught exception propagates up the activation path to its nearest root activity, where it may be handled locally or propagated up the root-of tree when the activity terminates (based on the semantics of the statement being executed by the activity).\(^2\) There is always a good place to put a try-catch block to catch exceptions thrown by an asynchronous activity.

14.2 async: Spawning an activity

Asynchronous activities serve as a single abstraction for supporting a wide range of concurrency constructs such as message passing, threads, DMA, streaming, and data prefetching. (In general, asynchronous operations are better suited for supporting scalability than synchronous operations.)

An activity is created by executing the async statement:

\[
\text{AsyncStmt} ::= \text{async ClockedClause? Stmt} \quad (20.15) \\
\text{ClockedClause} ::= \text{clocked async Stmt} \quad (20.39)
\]

\(^1\)Note that depending on the state of the computation the activation path may traverse activities that are running, blocked or terminated.

\(^2\)In X10 v2.4 the finish statement is the only statement that marks its activity as a root activity. Future versions of the language may introduce more such statements.
The basic form of async is async $S$, which starts a new activity located here executing $S$. (For the clocked form, see §15.4.)

Multiple activities launched by a single activity in a place are not ordered in any way. They are added to the set of activities running in the place and will be executed based on the local scheduler’s decisions. If some particular sequencing of events is needed, when, atomic, finish, clocks, and other X10 constructs can be used. X10 implementations are not required to have fair schedulers, though every implementation should make a best faith effort to ensure that every activity eventually gets a chance to make forward progress.

The statement in the body of an async is subject to the restriction that it must be acceptable as the body of a void method for an anonymous inner class declared at that point in the code. For example, it may reference val variables in lexically enclosing scopes, but not var variables. Similarly, it cannot break or continue surrounding loops.

14.3 Finish

The statement finish $S$ converts global termination to local termination.

\[
\text{FinishStmt} ::= \text{finish Stmt} \mid \text{clocked finish Stmt}
\]  

(20.72)

An activity $A$ executes finish $S$ by executing $S$ and then waiting for all activities spawned by $S$ (directly or indirectly, here or at other places) to terminate. An activity may terminate normally, or abruptly, i.e. by throwing an exception. All exceptions thrown by spawned activities are caught and accumulated.

finish $S$ terminates locally when all activities spawned by $S$ terminate globally (either abruptly or normally). If $S$ terminates normally, then finish $S$ terminates normally and $A$ continues execution with the next statement after finish $S$. If $S$ or one of the activities spawned by it terminate abruptly, then finish $S$ terminates abruptly and throws a single exception, of type x10.lang.MultipleExceptions, formed from the collection of exceptions accumulated at finish $S$.

Thus finish $S$ statement serves as a collection point for uncaught exceptions generated during the execution of $S$.

Note that repeatedly finishing a statement has little effect after the first finish: finish finish $S$ is indistinguishable from finish $S$ if $S$ terminates normally. If $S$ throws exceptions, finish $S$ collects the exceptions and wraps them in a MultipleExceptions, whereas finish finish $S$ does the same, and then puts that MultipleExceptions inside of a second MultipleExceptions.
14.4 Initial activity

An X10 computation is initiated from the command line on the presentation of a class or struct name C. The container must have a `main` method:

```java
public static def main(a: Rail[String]):void
```

method, otherwise an exception is thrown and the computation terminates. The single statement

```java
finish async at (Place.FIRST_PLACE) {
    C.main(s);
}
```

is executed where s is a one-dimensional Rail of strings created from the command line arguments. This single activity is the root activity for the entire computation. (See §13 for a discussion of places.)

14.5 Ateach statements

**Deprecated:** The `ateach` construct is deprecated.

```plaintext
AtEachStmt ::= ateach ( LoopIndex in Exp ) ClockedClause? Stmt
               | ateach ( Exp ) Stmt

LoopIndexDeclr ::= Id HasResultType?
                 | [IdList] HasResultType'
                 | Id [IdList] HasResultType'

LoopIndex ::= Mods? LoopIndexDeclr
             | Mods? VarKeyword LoopIndexDeclr
```

In `ateach(p in D) S`, D must be either of type `Dist` (see §16.4.3) or of type `DistArray[T]` (see §16), and p will be of type `Point` (see §16.3.1). If D is an `DistArray[T]`, then `ateach (p in D)S` is identical to `ateach(p in D.dist)S`; the iteration is over the array’s underlying distribution.

Instead of writing `ateach (p in D) S` the programmer could write

```java
for (place in D.places()) at (place) async {
    for (p in D|here) async {
        S(p);
    }
}
```

For each point p in D, statement S is executed concurrently at place D(p).

`break` and `continue` statements may not be applied to `ateach`. 
14.6 vars and Activities

X10 restricts the use of local var variables in activities, to make programs more deterministic. Specifically, a local var variable \( x \) defined outside of async \( S \) cannot appear inside async \( S \) unless there is a finish surrounding async \( S \) with the definition of \( x \) outside of it.

**Example:** The following code is fine; the definition of result appears outside of the finish block:

```plaintext
var result : Long = 0;
finish {
    async result = 1;
}
assert result == 1;
```

This code is deterministic: the async will finish before the assert starts, and the assert's test will be true.

However, without the finish, the code would not compile in X10. If it were allowed to compile, the activity might finish or might not finish before the println, and the program would not be deterministic.

14.7 Atomic blocks

X10's atomic blocks (atomic \( S \) and when \( (c) S \)) provide a high-level construct for coordinating the mutation of shared data. An atomic block is executing as if in a single step, with respect to atomic blocks executed by all other activities in the same place. That is, all atomic blocks execute in a serializable order. Hence no atomic block can see the intermediate state within the execution of some other atomic block.

Code executed inside of atomic \( S \) and when \( (E) S \) is subject to certain restrictions. A violation of these restrictions causes an IllegalOperationException to be thrown at the point of the violation.

- \( S \) may not spawn another activity.
- \( S \) may not use any blocking statements: when, Clock.advanceAll(), finish. (The use of a nested atomic is permitted.)
- \( S \) may not force() a Future.
- \( S \) may not use at expressions.

That is \( S \) must be sequential, single-place and non-blocking.

A programmer may use atomic blocks to guarantee that invariants of shared data-structures are maintained even as they are being accessed simultaneously by multiple
activities running in the same place. An X10 program in which all accesses (both reads and writes) of shared variables appear in atomic or when blocks is guaranteed to use all shared variables atomically. Equivalently, if two accesses to some shared variable \( v \) could collide at runtime, and one is in an atomic block, then the other must be in an atomic block as well to guarantee atomicity of the accesses to \( v \). If some accesses to shared variables are not protected by atomic or when, then race conditions or deadlocks may occur. In particular, atomic blocks at the same place are atomic with respect to each other. They may not be atomic with respect to non-atomic code, or with respect to atomic sections at different places.

\[
\begin{align*}
\text{AtomicStmt} & : = \text{atomic \ Stmt} \quad \text{(20.21)} \\
\text{WhenStmt} & : = \text{when ( Exp ) Stmt} \quad \text{(20.207)}
\end{align*}
\]

**Example:** Consider a class `Redund[T]`, which encapsulates a list `list` and, redundantly keeps the size of the list in a second field `size`. Then `r:Redund[T]` has the invariant `r.list.size() == r.size`, which must be true at any point at which no method calls on `r` are active.

If the `add` method on `Redund` (which adds an element to the list) were defined as:

\[
def add(x:T) \{ // Incorrect
  \text{this.list.add}(x);
  \text{this.size} = \text{this.size} + 1;
\}
\]

Then two activities simultaneously adding elements to the same `r` could break the invariant. Suppose that `r` starts out empty. Let the first activity perform the `list.add` and compute `this.size+1`, which is 1, but not store it back into `this.size` yet. (At this point, `r.list.size()==1` and `r.size==0`; the invariant expression is false, but, as the first call to `r.add()` is active, the invariant does not need to be true – it only needs to be true when the call finishes.) Now, let the second activity do its call to `add` to completion, which finishes with `r.size==1`. (As before, the invariant expression is false, but a call to `r.add()` is still active, so the invariant need not be true.) Finally, let the first activity finish, which assigns the 1 computed before back into `this.size`.

At the end, there are two elements in `r.list`, but `r.size==1`. Since there are no calls to `r.add()` active, the invariant is required to be true, but it is not.

In this case, the invariant can be maintained by making the increment atomic. Doing so forbids that sequence of events; the atomic block cannot be stopped partway.

\[
def add(x:T) \{
  \text{atomic} \{
    \text{this.list.add}(x);
    \text{this.size} = \text{this.size} + 1;
  \}
\}
14.7.1 Unconditional atomic blocks

The simplest form of an atomic block is the unconditional atomic block: atomic \( S \). It executes \( S \) as if in a single step with respect to all other concurrently executing atomic blocks. \( S \) may throw an exception; when control leaves atomic \( S \) the side-effects executed so far are made visible to other atomic blocks. The programmer may surround \( S \) with a try/finally block and try to undo assignments when an exception is thrown.

Atomic blocks are closely related to non-blocking synchronization constructs [7], and can be used to implement non-blocking concurrent algorithms.

Note an important property of an (unconditional) atomic block:

\[
\text{atomic } \{ s_1; \text{atomic } s_2 \} = \text{atomic } \{ s_1; s_2 \} \quad (14.1)
\]

Unconditional atomic blocks do not introduce deadlocks. They may exhibit all the bad behavior of sequential programs, including throwing exceptions and running forever, but they are guaranteed not to deadlock.

**Example:** The following class method implements a (generic) compare and swap (CAS) operation:

```scala
var target:Any = null;
public atomic def CAS(old1: Any, y: Any):Boolean {
    if (target.equals(old1)) {
        target = y;
        return true;
    }
    return false;
}
```

14.7.2 Conditional atomic blocks

Conditional atomic blocks are of the form when(b)\( S \); \( b \) is called the guard, and \( S \) the body.

An activity executing such a statement suspends until such time as the guard is true in the current state. In that state, the body is executed. The checking of the guards and the execution of the corresponding guarded statement is done atomically.

X10 does not guarantee that a conditional atomic block will execute if its condition holds only intermittently. For, based on the vagaries of the scheduler, the precise instant at which a condition holds may be missed. Therefore the programmer is advised to ensure that conditions being tested by conditional atomic blocks are eventually stable, *i.e.* they will continue to hold until the block executes (the action in the body of the block may cause the condition to not hold any more).
The statement \( \text{when } (\text{true}) \) \( S \) is behaviorally identical to \( \text{atomic } S \): it never suspends.

The body \( S \) of \( \text{when}(b)S \) is subject to the same restrictions that the body of \( \text{atomic } S \) is. The guard is subject to the same restrictions as well. Furthermore, guards should not have side effects. Note that this implies that guarded statements are required to be flat, that is, they may not contain conditional atomic blocks. (The implementation of nested conditional atomic blocks may require sophisticated operational techniques such as rollbacks.)

Conditional atomic blocks allow the activity to wait for some condition to be satisfied before executing an atomic block. For example, consider a \texttt{Redund} class holding a list \( r\text{.list} \) and, redundantly, its length \( r\text{.size} \). A \texttt{pop} operation will delay until the \texttt{Redund} is nonempty, and then remove an element and update the length.

```x10
def pop():T {
    var ret : T;
    when(size>0) {
        ret = list.removeAt(0);
        size --;
    }
    return ret;
}
```

The execution of the test is atomic with the execution of the block. This is important; it means that no other activity can sneak in and falsify the condition after the test was seen to be true, but before the block is executed. In this example, two \texttt{pop}s executing on a list with one element would work properly. Without the conditional atomic block – even doing the decrement atomically – one call to \texttt{pop} could pass the \( \text{size}>0 \) guard; then the other call could run to completion (removing the only element of the list); then, when the first call proceeds, its \texttt{removeAt} will fail.

Note that \texttt{if} would not work here.

```x10
if(size>0) atomic{size--; return list.removeAt(0);}
```

allows another activity to act between the test and the atomic block. And

```x10
atomic{ if(size>0) {size--; ret = list.removeAt(0);}}
```

does not wait for \( \text{size}>0 \) to become true.

**Example:** The following class shows how to implement a bounded buffer of size 1 in X10 for repeated communication between a sender and a receiver. The call \texttt{buf.send(ob)} waits until the buffer has space, and then puts \( ob \) into it. Dually, \texttt{buf.receive()} waits until the buffer has something in it, and then returns that thing.

```x10
class OneBuffer[T] {
    var datum: T;
    def this(t:T) { this.datum = t; this.filled = true; }
    var filled: Boolean;
```
public def send(v: T) {
    when (!filled) {
        this.datum = v;
        this.filled = true;
    }
}
public def receive(): T {
    when (filled) {
        v: T = datum;
        filled = false;
        return v;
    }
}

When is Tested

Suppose that activity $A$ is blocked waiting on when(e)S, because $e$ is false. If some other activity $B$ changes the state in an atomic section in a way that makes $e$ become true, then either:

- $A$ will eventually execute $S$, or
- Some activity $C \neq A$ will cause $e$ to become false again, or
- Some activity at that place will execute an infinite number of steps.

In particular, if no other activity ever falsifies $e$, then $A$ will, eventually, discover that $e$ evaluates to true and run $S$ (provided that no other activity at that place is running forever).

Two caveats are worth noting:

- X10 has no guarantees of fairness or liveness.
- X10 only makes guarantees about state changes in atomic blocks alerting whens. State changes outside of atomic blocks might not cause $A$ to re-evaluate $e$.

Example: The method good below will always terminate (assuming no other activities are executing an infinite number of steps). In particular, if the when statement is allowed to run first and block on c(), the atomic will alert it that c() has changed.

The method bad has no such guarantee: it might terminate if the compiler and scheduler are in a generous mood, or the when might wait forever to be told that c() is now true. Without an atomic, the when statement might not be notified about the change in c().
14.8. USE OF ATOMIC BLOCKS

The semantics of atomicity is chosen as a compromise between programming simplicity and efficient implementation. Unlike some possible definitions of “atomic”, atomic blocks do not provide absolute atomicity.

Atomic blocks are atomic with respect to each other.

```java
static def good() {
    val c = new Cell[Boolean](false);
    async {
        atomic {c() = true;}
    }
    when( c() );
}
static def bad() {
    val c = new Cell[Boolean](false);
    async {
        c() = true;
    }
    when( c() );
}
```

This program has only two possible interleavings: either (a) entirely precedes (b) or (b) entirely precedes (a). Both end up with n=3.

However, atomic blocks are not atomic with respect to non-atomic code. If we remove the atomics on (a), we get far messier semantics.

```java
var n : Long = 0;
finish {
    async atomic n = n + 1; // (a)
    async atomic n = n + 2; // (b)
}
```

If X10 had absolute (“strong”) atomic semantics, this program would be guaranteed to treat the atomic increment as a single statement. This would permit three interleavings: the two possible from the fully atomic program, or a third one with the events: (a)’s read of 0 from n, the entirety of (b), and then (a)’s write of 0+1 back to n. This
interleaving results in \( n=1 \). So, with absolute atomic semantics, \( n=1 \) or \( n=3 \) are the possible results.

However, atomic blocks in X10 are “weak”. Atomic blocks are atomic with respect to each other — but there is no guarantee about how they interact with non-atomic statements at all. They might even break up the atomicity of an atomic block. In particular, the following fourth interleaving is possible: (a)’s read of 0 from \( n \), (b)’s read of 0 from \( n \), (a)’s write of 1 to \( n \), and (b)’s write of 2 to \( n \). Thus, \( n=2 \) is permissible as a result in X10.

However, X10’s semantics do impose a certain burden on the programmer. A sufficient rule of thumb is that, if any access to a variable is done in an atomic section, then all accesses to it must be in atomic sections.

Atomic sections are a powerful and convenient general solution. Classes in the package \texttt{x10.util.concurrent} may be more efficient and more convenient in particular cases. For example, an \texttt{AtomicInteger} provides an atomic integer cell, with atomic get, set, compare-and-set, and add operations. Each \texttt{AtomicInteger} takes care of its own locking. Accesses to one \texttt{AtomicInteger} \texttt{a} only block activities which try to access \texttt{a} — not others, not even if they are using different \texttt{AtomicIntegers} or even atomic blocks.
15 Clocks

Many concurrent algorithms proceed in phases: in phase \( k \), several activities work independently, but synchronize together before proceeding on to phase \( k + 1 \). X10 supports this communication structure (and many variations on it) with a generalization of barriers called clocks. Clocks are designed to be dynamic (new activities can be registered with clocks, and terminated activities automatically deregister from clocks), and to support a simple syntactic discipline for deadlock-free and race-free conditions. Just like \texttt{finish}, X10’s clocks can both be used within a single place and to synchronize activities across multiple places.

The following minimalist example of clocked code has two worker activities A and B, and three phases. In the first phase, each worker activity says its name followed by 1; in the second phase, by a 2, and in the third, by a 3. So, if \texttt{say} prints its argument, \texttt{A-1 B-1 A-2 B-2 B-3 A-3} would be a legitimate run of the program, but \texttt{A-1 A-2 B-1 B-2 A-3 B-3} (with \texttt{A-2} before \texttt{B-1}) would not.

The program creates a clock \texttt{cl} to manage the phases. Each participating activity does the work of its first phase, and then executes \texttt{Clock.advanceAll();} to signal that it is finished with that work. \texttt{Clock.advanceAll();} is blocking, and causes the participant to wait until all participant have finished with the phase – as measured by the clock \texttt{cl} to which they are both registered. Then they do the second phase, and another \texttt{Clock.advanceAll();} to make sure that neither proceeds to the third phase until both are ready. This example uses \texttt{finish} to wait for both participants to finish.

```java
class ClockEx {
    static def say(s: String) {
        Console.OUT.println(s);
    }

    public static def main(argv: Rail[String]) {
        finish async {
            val cl = Clock.make();
            async clocked(cl) { // Activity A
                say("A-1");
                Clock.advanceAll();
                say("A-2");
                Clock.advanceAll();
                say("A-3");
            }
            say("B-1");
            Clock.advanceAll();
            say("B-2");
            Clock.advanceAll();
            say("B-3");
        }
    }
}
```

215
This chapter describes the syntax and semantics of clocks and statements in the language that have parameters of type Clock.

The key invariants associated with clocks are as follows. At any stage of the computation, a clock has zero or more registered activities. An activity may perform operations only on those clocks it is registered with (these clocks constitute its clock set). An attempt by an activity to operate on a clock it is not registered with will cause a ClockUseException to be thrown. An activity is registered with zero or more (existing) clocks when it is created. During its lifetime, the only additional clocks it can possibly be registered with are exactly those that it creates. In particular it is not possible for an activity to register itself with a clock it discovers by reading a data structure.

The primary operations that an activity a may perform on a clock c that it is registered upon are:

- It may spawn and simultaneously register a new activity on c, with the statement async clocked(c).S.

- It may unregister itself from c, with c.drop(). After doing so, it can no longer use most operations on c.

- It may resume the clock, with c.resume(), indicating that it has finished with the current phase associated with c and is ready to move on to the next one.

- It may wait on the clock, with c.advance(). This first does c.resume(), and then blocks the current activity until the start of the next phase, viz., until all other activities registered on that clock have called c.resume().

- It may block on all the clocks it is registered with simultaneously, by the command Clock.advanceAll(). This, in effect, calls c.advance() simultaneously on all clocks c that the current activity is registered with.

- Other miscellaneous operations are available as well; see the Clock API.
15.1 Clock operations

There are two language constructs for working with clocks. `async clocked(c1) S` starts a new activity registered on one or more clocks. `Clock.advanceAll();` blocks the current activity until all the activities sharing clocks with it are ready to proceed to the next clock phase. Clocks are objects, and have a number of useful methods on them as well.

15.1.1 Creating new clocks

Clocks are created using a factory method on `x10.lang.Clock`:

```scala
val c: Clock = Clock.make();
```

The current activity is automatically registered with the newly created clock. It may deregister using the `drop` method on clocks (see the documentation of `x10.lang.Clock`). On (normal or abrupt) termination, an activity is automatically deregistered from all clocks it is registered with.

15.1.2 Registering new activities on clocks

The `async` statement with a `clocked` clause of either form, say

```scala
async clocked (c1, c2, c3) S
```

starts a new activity, initially registered with clocks c1, c2, and c3, and running S. The activity running this code must be registered on those clocks. Violations of these conditions are punished by the throwing of a `ClockUseException`.

If an activity a that has executed `c.resume()` then starts a new activity b also registered on c (e.g., via `async clocked(c) S`), the new activity b starts out having also resumed c, as if it too had executed `c.resume()`. That is, a and b are in the same phase of the clock.

```scala
// ACTIVITY a
val c = Clock.make();
c.resume();
async clocked(c) {
  // ACTIVITY b
c.advance();
b_phase_two();
  // END OF ACTIVITY b
```
} c.advance();
a_phase_two();
// END OF ACTIVITY a

In the proper execution, a and b both perform c.advance() and then their phase-2 actions. However, if b were not initially in the resume state for c, there would be a race condition; b could perform c.advance() and proceed to b_phase_two before a performed c.advance().

An activity may check whether or not it is registered on a clock c by the method call c.registered()

NOTE: X10 does not contain a “register” operation that would allow an activity to discover a clock in a datastructure and register itself (or another process) on it. Therefore, while a clock c may be stored in a data structure by one activity a and read from it by another activity b, b cannot do much with c unless it is already registered with it. In particular, it cannot register itself on c, and, lacking that registration, cannot register a sub-activity on it with async clocked(c) S.

15.1.3 Resuming clocks

X10 permits split phase clocks. An activity may wish to indicate that it has completed whatever work it wishes to perform in the current phase of a clock c it is registered with, without suspending itself altogether. It may do so by executing c.resume();

An activity may invoke resume() only on a clock it is registered with, and has not yet dropped ([15.1.5]. A ClockUseException is thrown if this condition is violated. Nothing happens if the activity has already invoked a resume on this clock in the current phase.

An activity may invoke Clock.resumeAll() to resume all the clocks that it is registered with and has not yet dropped. This resume()s all these clocks in parallel, or, equivalently, sequentially in some arbitrary order.

15.1.4 Advancing clocks

An activity may execute the following method call to signal that it is done with the current phase.

Clock.advanceAll();

Execution of this call blocks until all the clocks that the activity is registered with (if any) have advanced. (The activity implicitly issues a resume on all clocks it is registered with before suspending.)

Clock.advanceAll(); may be thought of as calling c.advance() in parallel for all clocks that the current activity is registered with. (The parallelism is conceptually
important: if activities $a$ and $b$ are both registered on clocks $c$ and $d$, and $a$ executes $c.advance(); d.advance()$ while $b$ executes $d.advance(); c.advance()$, then the two will deadlock. However, if the two clocks are waited on in parallel, as `Clock.advanceAll();` does, $a$ and $b$ will not deadlock.)

Equivalently, `Clock.advanceAll();` sequentially calls $c.resume()$ for each registered clock $c$, in arbitrary order, and then $c.advance()$ for each clock, again in arbitrary order.

An activity blocked on `advance()` resumes execution once it is marked for progress by all the clocks it is registered with.

### 15.1.5 Dropping clocks

An activity may drop a clock by executing `c.drop();`.

The activity is no longer considered registered with this clock. A `ClockUseException` is thrown if the activity has already dropped $c$.

### 15.2 Deadlock Freedom

In general, programs using clocks can deadlock, just as programs using loops can fail to terminate. However, programs written with a particular syntactic discipline are guaranteed to be deadlock-free, just as programs which use only bounded loops are guaranteed to terminate. The syntactic discipline is:

- The `advance()` instance method shall not be called on any clock. (The `Clock.advanceAll();` method is allowed for this discipline.)
- Inside of `finish(S)`, all clocked asyncs shall be in the scope some unclocked async in $S$.

X10 does not enforce this discipline. Doing so would exclude useful programs, many of which are deadlock-free for reasons more subtle than the straightforward syntactic discipline. Still, this discipline is useful for simple cases.

The first clause of the discipline prevents a deadlock in which an activity is registered on two clocks, advances one of them, and ignores the other. The second clause prevents the following deadlock.

```java
val c:Clock = Clock.make();
async clocked(c) { // (A)
  finish async clocked(c) { // (B) Violates clause 2
    Clock.advanceAll(); // (Bnext)
  }
  Clock.advanceAll(); // (Anext)
}
```
(A), first of all, waits for the finish containing (B) to finish. (B) will execute its advance at (Bnext), and then wait for all other activities registered on c to execute their advance()s. However, (A) is registered on c. So, (B) cannot finish until (A) has proceeded to (Anext), and (A) cannot proceed until (B) finishes. Thus, the activities are deadlocked.

### 15.3 Program equivalences

From the discussion above it should be clear that the following equivalences hold:

\[
\begin{align*}
\text{c.resume(); Clock.advanceAll();} & \quad = \quad \text{Clock.advanceAll();} \quad (15.1) \\
\text{c.resume(); d.resume();} & \quad = \quad \text{d.resume(); c.resume();} \quad (15.2) \\
\text{c.resume(); c.resume();} & \quad = \quad \text{c.resume();} \quad (15.3)
\end{align*}
\]

Note that \(\text{Clock.advanceAll(); Clock.advanceAll();}\) is not the same as \(\text{Clock.advanceAll();}\). The first will wait for clocks to advance twice, and the second once.

### 15.4 Clocked Finish

In the most common case of a single clock coordinating a few behaviors, X10 allows coding with an implicit clock. finish and async statements may be qualified with clocked.

A clocked finish introduces a new clock. It executes its body in the usual way that a finish does—except that, when its body completes, the activity executing the clocked finish drops the clock, while it waits for asynchronous spawned asyncs to terminate.

A clocked async registers its async with the implicit clock of the surrounding clocked finish.

The bodies of the clocked finish and clocked async statements may use the \(\text{Clock.advanceAll()}\) method call to advance the implicit clock. Since the implicit clock is not available in a variable, it cannot be manipulated directly. (If you want to manipulate the clock directly, use an explicit clock.)

**Example:** The following code starts two activities, each of which perform their first phase, wait for the other to finish phase 1, and then perform their second phase.

```plaintext
clocked finish {
    clocked async {
        phase("A", 1);
        Clock.advanceAll();
    }
    phase("B", 2);
    Clock.advanceAll();
}
```
15.4. Clocked Finish

```plaintext
phase("A", 2);
}
clocked async {
    phase("B", 1);
    Clock.advanceAll();
    phase("B", 2);
}
```

The clocked async and clocked finish constructs can be combined with at in the same ways as their unclocked counterparts.

**Example:** The following code creates one clocked activity in every Place that synchronize to execute iter steps of a two phase computation. The clock ensures that every activity has completed the call to before(N) before any activity calls after(N). Note that executions of after(N) and before(N+1) in different places may overlap; if this is not desired an additional call to Clock.advanceAll() could be added after the call to after(count).

```plaintext
clocked finish {
    for (p in Place.places()) {
        at (p) clocked async {
            for (count in 1..iters) {
                before(count);
                Clock.advanceAll();
                after(count);
            }
        }
    }
}
```

Clocked finishes may be nested. The inner clocked finish operates in a single phase of the outer one.
16 Rails and Arrays

16.1 Overview

Indexable memory is a fundamental abstraction provided by a programming language. To enable the programmer to best balance performance and flexibility, X10 provides a layered implementation of indexable memory. The foundation of all indexable storage in X10 is `x10.lang.Rail`, an intrinsic one-dimensional array analogous to the built-in arrays provided by languages such as C or Java. On top of Rail, more sophisticated array abstractions can be constructed completely as user-defined X10 classes. Two such families of user-defined array abstractions are included in the X10 core class libraries in the `x10.array` and `x10.regionarray` packages. Both families of arrays provide both local (single place) and distributed (multi-place) arrays.

The next section specifies Rail. Subsequent sections outline the `x10.array` and `x10.regionarray` packages. As discussed, in more detail below, Rail and the classes of `x10.array` provide significantly higher performance operations than the corresponding classes of `x10.regionarray`. Therefore we recommend that programmers only use the more general arrays of `x10.regionarray` where the increased flexibility justifies the reduced performance. We also encourage programmers to use the classes of `x10.array` as an example of how to define high-performance array abstractions in X10 and use them as templates for defining additional high-performance array abstractions (for example column-major arrays as in Fortran or 1-based arrays as in MATLAB).

16.2 Rails

The Rail class provides a basic abstraction of fixed-sized indexed storage. If r is a `Rail[T]`, then r contains r.size elements of type T that may be accessed using the Long values 0 to r.size-1 as indices. All accesses to the elements of a Rail are checked: attempting to use an index that is less than 0 or greater than r.size-1 will result in an `ArrayIndexOutOfBoundsException` being thrown.

As shown in the example below, instances of `Rail[T]` may be created using one of several constructors that initialize the data elements to the zero-value of T, a single initial value, or to a different initial value for each element of the Rail.
// A zero-initialized Rail of 10 doubles
val r1 = new Rail[Double](10);

// A Rail of 10 doubles, all initialized to pi
val r2 = new Rail[Double](10, Math.PI);

// A Rail of 10 doubles, r3(i) == i*pi
val r3 = new Rail[Double](10, (i:long)=>i*Math.PI);

As described in more detail in section 11.26, X10 also includes a shorthand form for Rail construction: simply put brackets around a list of expressions.

// A Rail[Long] containing the first 5 primes
val r1 = [2,3,5,7,11];

// A Rail[Double] such that r2(i) == i*pi
val r2 = [Math.PI, 2*Math.PI, 3*Math.PI, 4*Math.PI];

Accessing and updating single elements of a Rail is doing using application syntax. For example, a(i)=a(i+1); sets the i-th element of a to the value of the i+1 element of a. If T supports the + or - operation, then the usual pre/post increment/decrement operations are also available on individual array elements. For example, a(i)++ is equivalent to a(i) = a(i)+1

Iteration over the elements of a Rail can be accomplished using several equivalent idioms. Furthermore, via some modest compiler support, each of these for loops will actually result in identical generated code. In the examples below, r is a Rail[Long] and sum is a local variable of type Long.

// A classic C-style for loop
for (var i:long=0; i<r.size; i++) {
    sum += r(i);
}

// Iterate over the LongRange 0..(r.size-1)
for (i in 0..(r.size-1)) {
    sum += r(i);
}

// Get the LongRange to iterate over from r
for (i in r.range()) {
    sum += r(i);
}

// Directly iterate over the values of r
for (v in r) {
    sum += v;
}
Basic bulk operations such as clearing (setting to zero), filling with a single value, and copying are provided by methods of the Rail class. Efficient copying of Rails across places is supported via the combination of the `x10.lang.GlobalRail` struct and the `asyncCopy` method of Rail.

Additional complex bulk operations on Rail such as sorting, searching, map, and reduce are provided by the `x10.util.RailUtils` class.

When implementing higher-level data structures that use Rail as their backing storage, there may be significant performance advantage in performing unsafe operations on Rail. For example, when building a multi-dimensional Array class, the Array level bounds checking and initialization logic make the Rail level operations redundant. To support such scenarios the class `x10.lang.Unsafe` provides methods to allocate uninitialized Rail objects and to access the elements of a Rail without bounds checking. These unsafe extensions should be used judiciously, as improper use can result in memory safety violations that would not be possible in pure X10 code.

### 16.3 x10.array: Simple Arrays

Classes in the `x10.array` package provide high-performance implementations of both local and distributed multi-dimension arrays. The array implementations in this package are restricted to the case of rectangular, dense, zero-based index spaces. By making this restriction, the indexing calculations for both single-place and multi-place arrays can be optimized, resulting in an array implementation that should obtain equivalent performance to the corresponding array abstractions in C or Fortran. More general index spaces are supported by the classes in the `x10.regionarray` package (see Section 16.4).

The three main concepts of this package: iteration spaces, arrays, and distributed arrays are outlined below. All three concepts are implemented as simple class hierarchies with an abstract superclass and a collection of concrete final subclasses that contain the performance-critical operations. Client code using the abstractions can be written (with lower performance) using the abstract APIs provided by the superclass, but performance sensitive code should be written using the more specific type of the concrete subclasses. This enables compile time optimization and inlining of key operations, resulting in optimal code sequences.

#### 16.3.1 Points

Both kinds of arrays are indexed by Points, which are \( n \)-dimensional tuples of integers. The `rank` property of a point gives its dimensionality. Points can be constructed from integers, or `Rail[Long]` by the `\x outsider.Point.make` factory methods:

\[1\] A specialized version of `x10.lang.GlobalRef` that includes the size of the referenced Rail to enable bounds checking
16.3. X10.ARRAY: SIMPLE ARRAYS

val origin_1 : Point{rank==1} = Point.make(0);
val origin_2 : Point{rank==2} = Point.make(0,0);
val origin_5 : Point = Point.make(new Rail[Long](5));

There is an implicit conversion from Rail[Long] to Point, giving a convenient syntax for constructing points:

val p : Point = [1,2,3];
val q : Point{rank==5} = [1,2,3,4,5];
val r : Point(3) = [11,22,33];

The coordinates of a point are available by function application, or, if you prefer, by subscripting; p(i) is the ith coordinate of the point p. Point(n) is a type-defined shorthand for Point{rank==n}.

16.3.2 IterationSpace

An IterationSpace is a generalization of LongRange to multiple dimensions. The rank property of the IterationSpace corresponds to its dimensionality. An IterationSpace represents an ordered collection of Points of the same rank as the IterationSpace. The primary purpose of an IterationSpace is to represent the indices of an Array or DistArray.

16.3.3 Array

The abstract Array class provides rank-generic operations for single place multi-dimensional arrays. Its concrete subclasses Array_1, Array_2, etc. provide rank-specific operations such as efficient element access. The APIs of the classes are designed to be a natural extension of the Rail API to multiple dimensions. In most usage scenarios, programmers should operate using the types of the concrete subclasses, not of Array itself.

The example below illustrates the construction and indexing operations of rank 2 arrays using a simple matrix multiply kernel where N is a Long.

val a = new Array_2[double](N, N, (i:long,j:long)=>(i*j) as double);
val b = new Array_2[double](N, N, (i:long,j:long)=>(i-j) as double);
val c = new Array_2[double](N, N, (i:long,j:long)=>(i+j) as double);

for (i in 0..(N-1))
  for (j in 0..(N-1))
    for (k in 0..(N-1))
      a(i,j) += b(i,k)*c(k,j);

Similarly to Rail, iteration over the elements of a Array can be accomplished using several equivalent idioms. Furthermore, via some modest compiler support, each of these for loops will actually result in identical generated code. In the examples below, a is a Array_2[Long] and sum is a local variable of type Long.
// A classic C-style for loop
for (var i:long=0; i<a.numElems_1; i++) {
    for (var j:long=0; j<a.numElems_2; j++) {
        sum += a(i,j);
    }
}

// Iterate over the indices of a using Point destructuring
for ([i,j] in a.indices()) {
    sum += a(i,j);
}

// Directly iterate over the values of a
for (v in a) {
    sum += v;
}

An additional idiom which iterates over the Points in the IterationSpace of a without destructuring the Points is also supported, but should be avoid in the current implementation of X10 as the compiler does not optimize away all of the overheads associated with explicit use of Point objects.

// Iterate over the indices of a using Points
for (p in a.indices()) {
    sum += a(p);
}

16.3.4 DistArray

The abstract class DistArray and its concrete subclasses represent an extension of the Array API to multiple places. In X10 version 2.4.0 DistArrays are still a work in progress. Only three concrete implementations are available: DistArray.Unique which has one data element per Place, DistArray.Block_1 which block distributes a rank-1 array across the Places in its PlaceGroup, and DistArray.BlockBlock_2 which distributes blocks of a rank-2 array across the Places in its PlaceGroup.

The API of DistArray is preliminary in this release of X10 we anticipate extending it with more operations and supporting a wider range of ranks and distributions in future release of X10.

16.4 x10.regionarray: Flexible Arrays

Classes in the x10.regionarray package provide the most general and flexible array abstraction that support mapping arbitrary multi-dimensional index spaces to data elements. Although they are significantly more flexible than Rails or the classes of the
x10.array package, this flexibility does carry with it an expectation of lower runtime performance.

Arrays provide indexed access to data at a single Place, via Points—indices of any dimensionality. DistArrays is similar, but spreads the data across multiple Places, via Dists.

### 16.4.1 Regions

A region is a set of points of the same rank. X10 provides a built-in class, `x10.regionarray.Region`, to allow the creation of new regions and to perform operations on regions. Each region `R` has a property `R.rank`, giving the dimensionality of all the points in it.

Example:

```java
val MAX_HEIGHT=20;
val Null = Region.makeUnit(); // Empty 0-dimensional region
val R1 = Region.make(1, 100); // Region 1..100
val R2 = Region.make(1..100); // Region 1..100
val R3 = Region.make(0..99, -1..MAX_HEIGHT);
val R4 = Region.makeUpperTriangular(10);
val R5 = R4 && R3; // intersection of two regions
```

The `LongRange` value `1..100` can be used to construct the one-dimensional Region consisting of the points `{[m], ..., [n]}` Region by using the `Region.make` factory method. LongRanges are useful in building up regions, especially rectangular regions.

By a special dispensation, the compiler knows that, if `r : Region(m)` and `s : Region(n)`, then `r*s : Region(m+n)`. (The X10 type system ordinarily could not specify the sum; the best it could do would be `r*s : Region`, with the rank of the region unknown.) This feature allows more convenient use of arrays; in particular, one does not need to keep track of ranks nearly so much.

Various built-in regions are provided through factory methods on `Region`.

- `Region.makeEmpty(n)` returns an empty region of rank `n`.
- `Region.makeFull(n)` returns the region containing all points of rank `n`.
- `Region.makeUnit()` returns the region of rank `0` containing the unique point of rank `0`. It is useful as the identity for Cartesian product of regions.
- `Region.makeHalfspace(normal, k)`, where `normal` is a `Point` and `k` an `Long`, returns the unbounded half-space of rank `normal.rank`, consisting of all points `p` satisfying the vector inequality `p*normal ≤ k`.
- `Region.makeRectangular(min, max)`, where `min` and `max` are rank-1 length-`n` integer arrays, returns a `Region(n)` equal to: `[min(0) .. max(0), ..., min(n-1)..max(n-1)]`.

The `LongRange` value `1..100` can be used to construct the one-dimensional Region consisting of the points `{[m], ..., [n]}` Region by using the `Region.make` factory method. LongRanges are useful in building up regions, especially rectangular regions.
• Region.makeBanded(size, a, b) constructs the banded Region(2) of size
  size, with a bands above and b bands below the diagonal.
• Region.makeBanded(size) constructs the banded Region(2) with just the
  main diagonal.
• Region.makeUpperTriangular(N) returns a region corresponding to the non-
  zero indices in an upper-triangular N x N matrix.
• Region.makeLowerTriangular(N) returns a region corresponding to the non-
  zero indices in a lower-triangular N x N matrix.
• If R is a region, and p a Point of the same rank, then R+p is R translated forwards
  by p – the region whose points are r+p for each r in R.
• If R is a region, and p a Point of the same rank, then R-p is R translated backwards
  by p – the region whose points are r-p for each r in R.

All the points in a region are ordered canonically by the lexicographic total order. Thus
the points of the region (1..2)* (1..2) are ordered as

(1,1), (1,2), (2,1), (2,2)

Sequential iteration statements such as for ((1..2)) iterate over the points in a region
in the canonical order.

A region is said to be rectangular if it is of the form (T_1 * ... * T_k) for some set of
intervals T_i = l_i .. h_i. In particular an LongRange turned into a Region is rect-
angular: Region.make(1..10). Such a region satisfies the property that if two points
p_1 and p_3 are in the region, then so is every point p_2 between them (that is, it is convex).
(Banded and triangular regions are not rectangular.) The operation R.boundingBox() gives the smallest rectangular region containing R.

Operations on regions

Let R be a region. A sub-region is a subset of R.

Let R1 and R2 be two regions whose types establish that they are of the same rank. Let
S be another region; its rank is irrelevant.

R1 && R2 is the intersection of R1 and R2, viz., the region containing all points which
are in both R1 and R2. For example, Region.make(1..10) && Region.make(2..20)
is 2..10.

R1 * S is the Cartesian product of R1 and S, formed by pairing each point in R1 with
every point in S. Thus, Region.make(1..2)*Region.make(3..4)*Region.make(5..6)
is the region of rank 3 containing the eight points with coordinates [1,3,5], [1,3,6],
[1,4,5], [1,4,6], [2,3,5], [2,3,6], [2,4,5], [2,4,6].

For a region R and point p of the same rank, R+p and R-p represent the translation of
the region forward and backward by p. That is, R+p is the set of points p+q for all q in
R, and R-p is the set of q-p.

More Region methods are described in the API documentation.
16.4.2 Arrays

Arrays are organized data, arranged so that the data can be accessed with subscripts. An Array\(T\) \(A\) has a Region \(A.region\), specifying which Points are in \(A\). For each point \(p\) in \(A.region\), \(A(p)\) is the datum of type \(T\) associated with \(p\). X10 implementations should attempt to store Arrays efficiently, and to make array element accesses quick—e.g., avoiding constructing Points when unnecessary.

This generalizes the concepts of arrays appearing in many other programming languages. A Point may have any number of coordinates, so an Array can have, in effect, any number of integer subscripts.

Example: Indeed, it is possible to write code that works on Arrays regardless of dimension. For example, to add one Array[Long] src into another dest.

```java
static def addInto(src: Array[Long], dest:Array[Long])
{
    {src.region == dest.region}
    {
        for (p in src.region)
            dest(p) += src(p);
    }
}
```

Since \(p\) is a Point, it can hold as many coordinates as are necessary for the arrays src and dest.

The basic operation on arrays is subscripting: if \(A\) is an Array\(T\) and \(p\) a point with the same rank as \(A.region\), then \(A(p)\) is the value of type \(T\) associated with point \(p\). This is the same operation as function application (§10.2); arrays implement function types, and can be used as functions.

Array elements can be changed by assignment. If \(t:T\),

\[A(p) = t;\]

modifies the value associated with \(p\) to be \(t\), and leaves all other values in \(A\) unchanged.

An Array\(T\) named \(a\) has:

- \(a.region\): the Region upon which \(a\) is defined.
- \(a.size\): the number of elements in \(a\).
- \(a.rank\), the rank of the points usable to subscript \(a\). \(a.rank\) is a cached copy of \(a.region.rank\).

Array Constructors

To construct an array whose elements all have the same value \(init\), call new Array\(T\)(R, init). For example, an array of a thousand "oh!"s can be made by: new Array[String](1000, "oh!").
To construct and initialize an array, call the two-argument constructor: `new Array[T](R, f)` constructs an array of elements of type T on region R, with `a(p)` initialized to `f(p)` for each point p in R. f must be a function taking a point of rank `R.rank` to a value of type T.

**Example:** One way to construct the array [11, 22, 33] is with an array constructor `new Array[Long](3, (i:long)=>11*i)`. To construct a multiplication table, call `new Array[Long](Region.make(0..9, 0..9), (p:Point(2)) => p(0)*p(1))`.

Other constructors are available; see the API documentation and §11.26.

**Array Operations**

The basic operation on Arrays is subscripting. If `a:Array[T]` and `p:Point{rank == a.rank}`, then `a(p)` is the value of type T appearing at position p in a. The syntax is identical to function application, and, indeed, arrays may be used as functions. `a(p)` may be assigned to, as well, by the usual assignment syntax `a(p)=t`. (This uses the application and setting syntactic sugar, as given in §8.7.5.)

Sometimes it is more convenient to subscript by longs. Arrays of rank 1-4 can, in fact, be accessed by longs:

```scala
val A1 = new Array[Long](10, 0);
A1(4) = A1(4) + 1;
val A4 = new Array[Long](Region.make(1..2, 1..3, 1..4, 1..5), 0);
A4(2,3,4,5) = A4(1,1,1,1)+1;
```

Iteration over an Array is defined, and produces the Points of the array’s region. If you want to use the values in the array, you have to subscript it. For example, you could take the logarithm of every element of an `Array[Double]` by:

```scala
for (p in a) a(p) = Math.log(a(p));
```

The method `a.values()` can be used to enumerate all the values of an `Array[T]` array a.

```scala
static def allNonNegatives(a:Array[Double]):Boolean {
  for (v in a.values()) if (v < 0.0D) return false;
  return true;
}
```

**16.4.3 Distributions**

Distributed arrays are spread across multiple Places. A distribution, a mapping from a region to a set of places, describes where each element of a distributed array is kept. Distributions are embodied by the class `x10.regionarray.Dist` and its subclasses.
16.4. X10.REGIONLYNARRAY: FLEXIBLE ARRAYS

The rank of a distribution is the rank of the underlying region, and thus the rank of every point that the distribution applies to.

**Example:**

```scala
val R <: Region = Region.make(1..100);
val D1 <: Dist = Dist.makeBlock(R);
val D2 <: Dist = Dist.makeConstant(R, here);
```

*D1 distributes the region R in blocks, with a set of consecutive points at each place, as evenly as possible. D2 maps all the points in R to here.*

Let D be a distribution. D.region denotes the underlying region. Given a point p, the expression D(p) represents the application of D to p, that is, the place that p is mapped to by D. The evaluation of the expression D(p) throws an ArrayIndexOutOfBoundsException if p does not lie in the underlying region.

**PlaceGroups**

A PlaceGroup represents an ordered set of Places. PlaceGroups exist for performance and scalability: they are more efficient, in certain critical places, than general collections of Place. PlaceGroup implements Sequence[Place], and thus provides familiar operations – pg.size() for the number of places, pg.iterator() to iterate over them, etc.

PlaceGroup is an abstract class. The concrete class SparsePlaceGroup is intended for a small group of places. new SparsePlaceGroup(somePlace) is a good PlaceGroup containing one place. new SparsePlaceGroup(seqPlaces) constructs a sparse place group from a Rail of places.

**Operations returning distributions**

Let R be a region, Q a PlaceGroup, and P a place.

**Unique distribution**  The distribution Dist.makeUnique(Q) is the unique distribution from the region Region.make(1..k) to Q mapping each point i to pi.

**Constant distributions.** The distribution Dist.makeConstant(R,P) maps every point in region R to place P. The special case Dist.makeConstant(R) maps every point in R to here.

**Block distributions.** The distribution Dist.makeBlock(R) distributes the elements of R, in approximately-even blocks, over all the places available to the program. There are other Dist.makeBlock methods capable of controlling the distribution and the set of places used; see the API documentation.
**Domain Restriction.** If $D$ is a distribution and $R$ is a sub-region of $D$.region, then $D \mid R$ represents the restriction of $D$ to $R$—that is, the distribution that takes each point $p$ in $R$ to $D(p)$, but doesn’t apply to any points but those in $R$.

**Range Restriction.** If $D$ is a distribution and $P$ a place expression, the term $D \mid P$ denotes the sub-distribution of $D$ defined over all the points in the region of $D$ mapped to $P$.

Note that $D \mid$ here does not necessarily contain adjacent points in $D$.region. For instance, if $D$ is a cyclic distribution, $D \mid$ here will typically contain points that differ by the number of places. An implementation may find a way to still represent them in contiguous memory, e.g., using an arithmetic function to map from the region index to an index into the array.

### 16.4.4 Distributed Arrays

Distributed arrays, instances of DistArray[T], are very much like Arrays, except that they distribute information among multiple Places according to a Dist value passed in as a constructor argument.

**Example:** The following code creates a distributed array holding a thousand cells, each initialized to 0.0, distributed via a block distribution over all places.

```
val R <: Region = Region.make(1..1000);
val D <: Dist = Dist.makeBlock(R);
val da <: DistArray[Float] = DistArray.make[Float](D, (Point(1))=>0.0f);
```

### 16.4.5 Distributed Array Construction

DistArrays are instantiated by invoking one of the make factory methods of the DistArray class. A DistArray creation must take either an Long as an argument or a Dist. In the first case, a distributed array is created over the distribution Dist.makeConstant(Region.make(0, N-1),here); in the second over the given distribution.

**Example:** A distributed array creation operation may also specify an initializer function. The function is applied in parallel at all points in the domain of the distribution. The construction operation terminates locally only when the DistArray has been fully created and initialized (at all places in the range of the distribution).

For instance:

```
val ident = ([i]:Point(1)) => i;
val data : DistArray[Long] = DistArray.make[Long](Dist.makeConstant(Region.make(1, 9)), ident);
val blk = Dist.makeBlock(Region.make(1..9, 1..9));
val data2 : DistArray[Long] = DistArray.make[Long](blk, ([i,j]:Point(2)) => i*j);
```
16.4. X10.REGIONARRAY: FLEXIBLE ARRAYS

The first declaration stores in data a reference to a mutable distributed array with 9 elements each of which is located in the same place as the array. The element at \([i]\) is initialized to its index \(i\).

The second declaration stores in data2 a reference to a mutable two-dimensional distributed array, whose coordinates both range from 1 to 9, distributed in blocks over all Places, initialized with \(i*j\) at point \([i,j]\).

16.4.6 Operations on Arrays and Distributed Arrays

Arrays and distributed arrays share many operations. In the following, let \(a\) be an array with base type \(T\), and \(da\) be an array with distribution \(D\) and base type \(T\).

Element operations

The value of \(a\) at a point \(p\) in its region of definition is obtained by using the indexing operation \(a(p)\). The value of \(da\) at \(p\) is similarly \(da(p)\). This operation may be used on the left hand side of an assignment operation to update the value: \(a(p) = t\); and \(da(p) = t\); The operator assignments, \(a(i) += e\) and so on, are also available.

It is a runtime error to access arrays, with \(da(p)\) or \(da(p) = v\), at a place other than \(da.dist(p)\), \(viz.\) at the place that the element exists.

Arrays of Single Values

For a region \(R\) and a value \(v\) of type \(T\), the expression \(\text{new Array}[T](R, v)\) produces an array on region \(R\) initialized with value \(v\). Similarly, for a distribution \(D\) and a value \(v\) of type \(T\) the expression

\[\text{DistArray.make}[T](D, (\text{Point}(D.rank))=>v)\]

constructs a distributed array with distribution \(D\) and base type \(T\) initialized with \(v\) at every point.

Note that Arrays are constructed by constructor calls, but DistArrays are constructed by calls to the factory methods DistArray.make. This is because Arrays are fairly simple objects, but DistArrays may be implemented by different classes for different distributions. The use of the factory method gives the library writer the freedom to select appropriate implementations.

Restriction of an array

Let \(R\) be a sub-region of \(da.region\). Then \(da | R\) represents the sub-DistArray of \(da\) on the region \(R\). That is, \(da | R\) has the same values as \(da\) when subscripted by a point in region \(R \&\& da.region\), and is undefined elsewhere.

Recall that a rich set of operators are available on distributions (§16.4.3) to obtain sub-distributions (e.g. restricting to a sub-region, to a specific place etc).
Operations on Whole Arrays

Pointwise operations  The unary map operation applies a function to each element of a distributed or non-distributed array, returning a new distributed array with the same distribution, or a non-distributed array with the same region.

The following produces an array of cubes:

```scala
val A = new Array[Long](11, (i:long)=>i);
assert A(3) == 3 && A(4) == 4 && A(10) == 10;
val cube = (i:Long) => i*i*i;
val B = A.map(cube);
assert B(3) == 27 && B(4) == 64 && B(10) == 1000;
```

A variant operation lets you specify the array into which the result will be stored,

```scala
val A = new Array[Long](11, (i:long)=>i);
assert A(3) == 3 && A(4) == 4 && A(10) == 10;
val cube = (i:Long) => i*i*i;
val B = new Array[Long](A.region); // B = 0,0,0,0,0,0,0,0,0,0,0
A.map(B, cube);
assert B(3) == 27 && B(4) == 64 && B(10) == 1000;
```

This is convenient if you have an already-allocated array lying around unused. In particular, it can be used if you don’t need A afterwards and want to reuse its space:

```scala
val A = new Array[Long](11, (i:long)=>i);
assert A(3) == 3 && A(4) == 4 && A(10) == 10;
val cube = (i:Long) => i*i*i;
A.map(A, cube);
assert A(3) == 27 && A(4) == 64 && A(10) == 1000;
```

The binary map operation takes a binary function and another array over the same region or distributed array over the same distribution, and applies the function pointwise to corresponding elements of the two arrays, returning a new array or distributed array of the same shape. The following code adds two distributed arrays:

```scala
static def add(da:DistArray[Long], db: DistArray[Long])
{da.dist==db.dist}
    = da.map(db, (a:Long,b:Long)=>a+b);
```

Reductions  Let $f$ be a function of type $(T, T)\Rightarrow T$. Let $a$ be an array over base type $T$. Let $unit$ be a value of type $T$. Then the operation $a.reduce(f, unit)$ returns a value of type $T$ obtained by combining all the elements of $a$ by use of $f$ in some unspecified order (perhaps in parallel). The following code gives one method which meets the definition of reduce, having a running total $r$, and accumulating each value $a(p)$ into it using $f$ in turn. (This code is simply given as an example; Array has this operation defined already.)
def oneWayToReduce[T](a:Array[T], f:(T,T)=>T, unit:T):T {
    var r : T = unit;
    for(p in a.region) r = f(r, a(p));
    return r;
}

For example, the following sums an array of longs. \( f \) is addition, and \( \text{unit} \) is zero.

```scala
val a = new Array[Long](4, (i:long)=>i+1);
val sum = a.reduce((a:Long,b:Long)=>a+b, 0);
assert(sum == 10); // 10 == 1+2+3+4
```

Other orders of evaluation, degrees of parallelism, and applications of \( f(x, \text{unit}) \) and \( f(\text{unit}, x) \) are also correct. In order to guarantee that the result is precisely determined, the function \( f \) should be associative and commutative, and the value \( \text{unit} \) should satisfy \( f(\text{unit}, x) == x == f(x, \text{unit}) \) for all \( x:T \).

DistArrays have the same operation. This operation involves communication between the places over which the DistArray is distributed. The X10 implementation guarantees that only one value of type \( T \) is communicated from a place as part of this reduction process.

**Scans** Let \( f:(T,T)=>T, \text{unit}:T, \) and \( a \) be an Array[T] or DistArray[T]. Then \( a.\text{scan}(f, \text{unit}) \) is the array or distributed array of type T whose \( i \)th element in canonical order is the reduction by \( f \) with unit \( \text{unit} \) of the first \( i \) elements of \( a \).

This operation involves communication between the places over which the distributed array is distributed. The X10 implementation will endeavour to minimize the communication between places to implement this operation.

Other operations on arrays, distributed arrays, and the related classes may be found in the x10.regionarray package.
17 Annotations

X10 provides an annotation system for allowing the compiler to be extended with new static analyses and new transformations.

Annotations are constraint-free interface types that decorate the abstract syntax tree of an X10 program. The X10 type-checker ensures that an annotation is a legal interface type. In X10, interfaces may declare both methods and properties. Therefore, like any interface type, an annotation may instantiate one or more of its interface’s properties.

17.1 Annotation syntax

The annotation syntax consists of an “@” followed by an interface type.

\[
\begin{align*}
\text{Annotations} & ::= \text{Annotation} \quad \text{(20.6)} \\
& | \quad \text{Annotations Annotation} \\
\text{Annotation} & ::= \text{@ NamedTypeNoConstraints} \quad \text{(20.4)}
\end{align*}
\]

Annotations can be applied to most syntactic constructs in the language including class declarations, constructors, methods, field declarations, local variable declarations and formal parameters, statements, expressions, and types. Multiple occurrences of the same annotation (i.e., multiple annotations with the same interface type) on the same entity are permitted.

Recall that interface types may have dependent parameters.

The following examples illustrate the syntax:

- Declaration annotations:

  ```
  // class annotation
  @Value
  class Cons { ... }
  
  // method annotation
  @PreCondition(0 <= i && i < this.size)
  public def get(i: Long): T { ... }
  ```

236
// constructor annotation
@Where(x != null)
def this(x: T) { ... }

// constructor return type annotation
def this(x: T): C@Initialized { ... }

// variable annotation
@Unique x: A;

• Type annotations:
  List@Nonempty
  Int@Range(1n,4n)
  Rail[Rail[Double]]@Size(n * n)

• Expression annotations:
m() @RemoteCall

• Statement annotations:
  @Atomic { ... }
  @MinIterations(0)
  @MaxIterations(n)
  for (var i: Long = 0; i < n; i++) { ... }

  // An annotated empty statement ;
  @Assert(x < y);

17.2 Annotation declarations

Annotations are declared as interfaces. They must be subtypes of the interface x10.lang.annotation.Annotation. Annotations on particular static entities must extend the corresponding Annotation subclasses, as follows:

• Expressions—ExpressionAnnotation
• Statements—StatementAnnotation
• Classes—ClassAnnotation
CHAPTER 17. ANNOTATIONS

- Fields—FieldAnnotation
- Methods—MethodAnnotation
- Imports—ImportAnnotation
- Packages—PackageAnnotation
The ability to interoperate with other programming languages is an essential feature of the X10 implementation. Cross-language interoperability enables both the incremental adoption of X10 in existing applications and the usage of existing libraries and frameworks by newly developed X10 programs.

There are two primary interoperability scenarios that are supported by X10 v2.4: inline substitution of fragments of foreign code for X10 program fragments (expressions, statements) and external linkage to foreign code.

### 18.1 Embedded Native Code Fragments

The @Native(lang,code) Construct annotation from x10.compiler.Native in X10 can be used to tell the X10 compiler to substitute code for whatever it would have generated when compiling Construct with the lang back end.

The compiler cannot analyze native code the same way it analyzes X10 code. In particular, @Native fields and methods must be explicitly typed; the compiler will not infer types.

#### 18.1.1 Native static Methods

Static methods can be given native implementations. Note that these implementations are syntactically expressions, not statements, in C++ or Java. Also, it is possible (and common) to provide native implementations into both Java and C++ for the same method.

```java
import x10.compiler.Native;
class Son {
    @Native("c++", "printf("Hi!\")")
    @Native("java", "System.out.println("Hi!\")")
    static def printNatively():void {}
}
```
If only some back-end languages are given, the X10 code will be used for the remaining back ends:

```java
import x10.compiler.Native;
class Land {
  @Native("c++", "printf("Hi from C++!")")
  static def example():void {
    x10.io.Console.OUT.println("Hi from X10!");
  }
}
```

The `native` modifier on methods indicates that the method must not have an X10 code body, and `@Native` implementations must be given for all back ends:

```java
import x10.compiler.Native;
class Plants {
  @Native("c++", "printf("Hi!")")
  @Native("java", "System.out.println("Hi!")")
  static native def printNatively():void;
}
```

Values may be returned from external code to X10. Scalar types in Java and C++ correspond directly to the analogous types in X10.

```java
import x10.compiler.Native;
class Return {
  @Native("c++", "1")
  @Native("java", "1")
  static native def one():Int;
}
```

Types are not inferred for methods marked as `@Native`.

Parameters may be passed to external code. (#1) is the first parameter, (#2) the second, and so forth. (#0) is the name of the enclosing class, or the `this` variable.) Be aware that this is macro substitution rather than normal parameter passing; e.g., if the first actual parameter is `i++`, and (#1) appears twice in the external code, `i` will be incremented twice. For example, a (ridiculous) way to print the sum of two numbers is:

```java
import x10.compiler.Native;
class Species {
  @Native("c++", "printf("Sum=%d", ((#1)+(#2)) )")
  @Native("java", "System.out.println("" + ((#1)+(#2)))")
  static native def printNatively(x:Int, y:Int):void;
}
```

Static variables in the class are available in the external code. For Java, the static variables are used with their X10 names. For C++, the names must be mangled, by use of the FMGL macro.
import x10.compiler.Native;

class Ability {
    static val A : Int = 1n;
    @Native("java", "A+2")
    @Native("c++", "Ability::FMGL(A)+2")
    static native def fromStatic():Int;
}

18.1.2 Native Blocks

Any block may be annotated with @Native(lang, stmt), indicating that, in the given back end, it should be implemented as stmt. All variables from the surrounding context are available inside stmt. For example, the method call born.example(10n), if compiled to Java, changes the field y of a Born object to 10. If compiled to C++ (for which there is no @Native), it sets it to 3.

import x10.compiler.Native;

class Born {
    var y : Int = 1n;
    public def example(x:Int):Int{
        @Native("java", "y=x;")
        {y = 3n;}
        return y;
    }
}

Note that the code being replaced is a statement – the block {y = 3n;} in this case – so the replacement should also be a statement.

Other X10 constructs may or may not be available in Java and/or C++ code. For example, type variables do not correspond exactly to type variables in either language, and may not be available there. The exact compilation scheme is not fully specified. You may inspect the generated Java or C++ code and see how to do specific things, but there is no guarantee that fancy external coding will continue to work in later versions of X10.

The full facilities of C++ or Java are available in native code blocks. However, there is no guarantee that advanced features behave sensibly. You must follow the exact conventions that the code generator does, or you will get unpredictable results. Furthermore, the code generator’s conventions may change without notice or documentation from version to version. In most cases the code should either be a very simple expression, or a method or function call to external code.
18.2 Interoperability with External Java Code

With Managed X10, we can seamlessly call existing Java code from X10, and call X10 code from Java. We call this the Java interoperability feature.

By combining Java interoperability with X10’s distributed execution features, we can even make existing Java applications, which are originally designed to run on a single Java VM, scale-out with minor modifications.

18.2.1 How Java program is seen in X10

Managed X10 does not pre-process the existing Java code to make it accessible from X10. X10 programs compiled with Managed X10 will call existing Java code as is.

Types In X10, both at compile time and run time, there is no way to distinguish Java types from X10 types. Java types can be referred to with regular import statement, or their qualified names. The package java.lang is not auto-imported into X10. In Managed x10, the resolver is enhanced to resolve types with X10 source files in the source path first, then resolve them with Java class files in the class path. Note that the resolver does not resolve types with Java source files, therefore Java source files must be compiled in advance. To refer to Java types listed in Tables 18.1 and 18.2 which include all Java primitive types, use the corresponding X10 type (e.g. use x10.lang.Int (or in short, Int) instead of int).

Fields Fields of Java types are seen as fields of X10 types.

Managed X10 does not change the static initialization semantics of Java types, which is per-class, at load time, and per-place (Java VM), therefore, it is subtly different than the per-field lazy initialization semantics of X10 static fields.

Methods Methods of Java types are seen as methods of X10 types.

Generic types Generic Java types are seen as their raw types (§4.8 in [6]). Raw type is a mechanism to handle generic Java types as non-generic types, where the type parameters are assumed as java.lang.Object or their upperbound if they have it. Java introduced generics and raw type at the same time to facilitate generic Java code interfacing with non-generic legacy Java code. Managed X10 uses this mechanism for a slightly different purpose. Java erases type parameters at compile time, whereas X10 preserves their values at run time. To manifest this semantic gap in generics, Managed X10 represents Java generic types as raw types and eliminates type parameters at source code level. For more detailed discussions, please refer to [14, 15].
import x10.interop.Java;
public class XClass {
    public static def main(args:Rail[String]):void {
        try {
            val a = Java.newArray[Int](2n);
            a(0n) = 0n;
            a(1n) = 1n;
            a(2n) = 2n;
        } catch (e:x10.lang.ArrayIndexOutOfBoundsException) {
            Console.OUT.println(e);
        }
    }
}

> x10c -d bin src/XClass.x10
> x10 -cp bin XClass
x10.lang.ArrayIndexOutOfBoundsException: Array index out of range: 2

Figure 18.1: Java exceptions in X10

**Arrays**  X10 rail and array types are generic types whose representation is different from Java array types.

Managed X10 provides a special X10 type `x10.interop.Java.array[T]` which represents Java array type `T[]`. Note that for X10 types in Table 18.1 this type means the Java array type of their primary type. For example, `array[Int]` and `array[String]` mean `int[]` and `java.lang.String[]`, respectively. Managed X10 also provides conversion methods between X10 Rails and Java arrays (`Java.convert[T](a:Rail[T]):array[T]` and `Java.convert[T](a:array[T]):Rail[T]`), and creation methods for Java arrays (`Java.newArray[T](d0:Int):array[T]` etc.).

**Exceptions**  The X10 v2.4 exception hierarchy has been designed so that there is a natural correspondence with the Java exception hierarchy. As shown in Table 18.2, many commonly used Java exception types are directly mapped to X10 exception types. Exception types that are thus aliased may be caught (and thrown) using either their Java or X10 types. In X10 code, it is stylistically preferable to use the X10 type to refer to the exception as shown in Figure 18.1.

**Compiling and executing X10 programs**  We can compile and run X10 programs that call existing Java code with the same `x10c` and `x10` command by specifying the location of Java class files or jar files that your X10 programs refer to, with `classpath` (or in short, `cp`) option.
18.2.2 How X10 program is translated to Java

Managed X10 translates X10 programs to Java class files. X10 does not provide a Java reflection-like mechanism to resolve X10 types, methods, and fields with their names at runtime, nor a code generation tool, such as javah, to generate stub code to access them from other languages. Java programmers, therefore, need to access X10 types, methods, and fields in the generated Java code directly as they access Java types, methods, and fields. To make it possible, Java programmers need to understand how X10 programs are translated to Java.

Some aspects of the X10 to Java translation scheme may change in future version of X10; therefore in this document only a stable subset of translation scheme will be explained. Although it is a subset, it has been extensively used by X10 core team and proved to be useful to develop Java Hadoop interop layer for a Main-memory Map Reduce (M3R) engine [11] in X10.

In the following discussions, we deliberately ignore generic X10 types because the translation of generics is an area of active development and will undergo some changes in future versions of X10. For those who are interested in the implementation of generics in Managed X10, please consult [13]. We also don’t cover function types, function values, and all non-static methods. Although slightly outdated, another paper [14], which describes translation scheme in X10 2.1.2, is still useful to understand the overview of Java code generation in Managed X10.

Types  X10 classes and structs are translated to Java classes with the same names. X10 interfaces are translated to Java interfaces with the same names.

Table 18.1 shows the list of special types that are mapped to Java primitives. Primitives are their primary representations that are useful for good performance. Wrapper classes are used when the reference types are needed. Each wrapper class has two static methods $box()$ and $unbox()$ to convert its value from primary representation to wrapper class, and vice versa, and Java backend inserts their calls as needed. An you notice, every unsigned type uses the same Java primitive as its corresponding signed type for its representation.

Table 18.2 shows a non-exhaustive list of another kind of special types that are mapped (not translated) to Java types. As you notice, since an interface Any is mapped to a class —java.lang.Object— and Object is hidden from the language, there is no direct way to create an instance of Object. As a workaround, Java.newObject() is provided. As you also notice, x10.lang.Comparable[T] is mapped to java.lang.Comparable. This is needed to map x10.lang.String, which implements x10.lang.Comparable[String], to java.lang.String for performance, but as a trade off, this mapping results in the lost of runtime type information for Comparable[T] in Managed X10. The runtime of Managed X10 has built-in knowledge for String, but for other Java classes that implement java.lang.Comparable, instanceof Comparable[Int] etc. may return incorrect results. In principle, it is impossible to map X10 generic type to the existing Java generic type without losing runtime type information.
### 18.2. INTEROPERABILITY WITH EXTERNAL JAVA CODE

#### Table 18.1: X10 types that are mapped to Java primitives

<table>
<thead>
<tr>

Table 18.2: X10 types that are mapped (not translated) to Java types
As shown in Figure 18.2, instance fields of X10 classes and structs are translated to the instance fields of the same names of the generated Java classes. Static fields of X10 classes and structs are translated to the static methods of the generated Java classes, whose name has `get$` prefix. Static fields of X10 interfaces are translated to the static methods of the special nested class named `$Shadow` of the generated Java interfaces.

**Note on name resolution** In X10, fields (both static and instance), local variables, and types are in the same name space, and fields and local variables have higher precedence than types in resolving names. This is same as in Java and it is programmers’ responsibility to avoid name conflict. Figure 18.3 explains how name conflict occurs. Uncommenting either `a` or `b`, or replacing `c` with `c’` causes `Field C not found in type “x10.lang.Long”` at `x`. Even if there is no name conflict in X10 code, it may occur in the generated Java code since Java backend generates static field access to get runtime type in some situation. To avoid potential name conflict, the best practice is not to use the same name for variables and package prefix.

**Methods** As shown in Figure 18.4, methods of X10 classes or structs are translated to the methods of the same names of the generated Java classes. Methods of X10 interfaces are translated to the methods of the same names of the generated Java interfaces.

Every method whose return type has two representations, such as the types in Table 18.1 will have `$0` suffix with its name. For example, `def f():Int` in X10 will
18.3. **INTEROPERABILITY WITH EXTERNAL C AND C++ CODE**

Main.x10:

```java
public class Main {
    //static val p:Long = 1; // a
    //val p:Long = 1; // b
    /\def func(p:Long) { // c'
    def func() { // c
        val f = p.C.f; // x
    }
}
```

p/C.x10:

```java
package p;
public class C {
    public static val f = true;
}
```

Figure 18.3: Name conflict in X10

be compiled as `int f$O()` in Java. For those who are interested in the reason, please look at our paper [15].

**Compiling Java programs** To compile Java program that calls X10 code, you should use `x10cj` command instead of `javac` (or whatever your Java compiler). It invokes the post Java-compiler of `x10c` with the appropriate options. You need to specify the location of X10-generated class files or jar files that your Java program refers to.

`x10cj -cp MyX10Lib.jar MyJavaProg.java`

**Executing Java programs** Before executing any X10-generated Java code, the runtime of Managed X10 needs to be set up properly at each place. To set up the runtime, a special launcher named `runjava` is used to run Java programs. All Java programs that call X10 code should be launched with it, and no other mechanisms, including direct execution with `java` command, are supported.

Usage: `runjava <Java-main-class> [arg0 arg1 ...]`

---

18.3 **Interoperability with External C and C++ Code**

C and C++ code can be linked to X10 code, either by writing auxiliary C++ files and adding them with suitable annotations, or by linking libraries.
interface I {
    def f():Int;
    def g():Any;
}
class C implements I {
    static def s():Int = 0n;
    static def t():Any = null;
    public def f():Int = 1n;
    public def g():Any = null;
}

interface I {
    int f$O();
    java.lang.Object g();
}
class C implements I {
    static int s$O() { return 0; }
    static java.lang.Object t() { return null; }
    public int f$O() { return 1; }
    public java.lang.Object g() { return null; }
}

Figure 18.4: X10 methods in Java
18.3. INTEROPERABILITY WITH EXTERNAL C AND C++ CODE

18.3.1 Auxiliary C++ Files

Auxiliary C++ code can be written in `.h` and `.cc` files, which should be put in the same directory as the the X10 file using them. Connecting with the library uses the `@NativeCPPInclude(dot_h_file_name)` annotation to include the header file, and the `@NativeCPPCompilationUnit(dot_cc_file_name)` annotation to include the C++ code proper. For example:

MyCppCode.h:

```cpp
void foo();
```

MyCppCode.cc:

```cpp
#include <cstdlib>
#include <cstdio>
void foo() {
    printf("Hello World!\n");
}
```

Test.x10:

```cpp
import x10.compiler.Native;
import x10.compiler.NativeCPPInclude;
import x10.compiler.NativeCPPCompilationUnit;

@NativeCPPInclude("MyCPPCode.h")
@NativeCPPCompilationUnit("MyCPPCode.cc")
public class Test {
    public static def main (args:Rail[String]) {
        { @Native("c++","foo();") } {}
    }
}
```

18.3.2 C++ System Libraries

If we want to additionally link to more libraries in `/usr/lib` for example, it is necessary to adjust the post-compilation directly. The post-compilation is the compilation of the C++ which the X10-to-C++ compiler `x10c++` produces.

The primary mechanism used for this is the `-cxx-prearg` and `-cxx-postarg` command line arguments to `x10c++`. The values of any `-cxx-prearg` commands are placed in the post compiler command before the list of `.cc` files to compile. The values of any `-cxx-postarg` commands are placed in the post compiler command after the list of `.cc` files to compile. Typically pre-args are arguments intended for the C++ compiler itself, while post-args are arguments intended for the linker.

The following example shows how to compile `blas` into the executable via these commands. The command must be issued on one line.
x10c++ Test.x10 -cxx-prearg -I/usr/local/blas
        -cxx-postarg -L/usr/local/blas -cxx-postarg -lblas'}
Definite Assignment

X10 requires that every variable be set before it is read. Sometimes this is easy, as when a variable is declared and assigned together:

```scala
var x : Long = 0;
assert x == 0;
```

However, it is convenient to allow programs to make decisions before initializing variables.

```scala
def example(a:Long, b:Long) {
  val max:Long;
  //ERROR: assert max==max; // can't read 'max'
  if (a > b) max = a;
  else max = b;
  assert max >= a && max >= b;
}
```

This is particularly useful for `val` variables. `var` could be initialized to a default value and then reassigned with the right value. `val`s must be initialized once and cannot be changed, so they must be initialized with the correct value.

However, one must be careful – and the X10 compiler enforces this care. Without the `else` clause, the preceding code might not give `max` a value by the time `assert` is invoked.

This leads to the concept of definite assignment [5]. A variable is definitely assigned at a point in code if, no matter how that point in code is reached, the variable has been assigned to. In X10, variables must be definitely assigned before they can be read.

As X10 requires that `val` variables not be initialized twice, we need the dual concept as well. A variable is definitely unassigned at a point in code if it cannot have been assigned no matter how that point in code is reached. For example, immediately after `val x:Long`, `x` is definitely unassigned.

Finally, we need the concept of singly and multiply assigned. A variable is singly assigned in a block if it is assigned precisely once; it is multiply assigned if it could possibly be assigned more than once. `var`s can multiply assigned as desired. `val`s
must be singly assigned. For example, the code \( x = 1; x = 2; \) is perfectly fine if \( x \) is a \texttt{var}, but incorrect (even in a constructor) if \( x \) is a \texttt{val}.

At some points in code, a variable might be neither definitely assigned nor definitely unassigned. Such states are not always useful.

\begin{verbatim}
def example(flag : Boolean) {
  var x : Long;
  if (flag) x = 1;
  // x is neither def. assigned nor unassigned.
  x = 2;
  // x is def. assigned.
}
\end{verbatim}

This shows that we cannot simply define “definitely unassigned” as “not definitely assigned”. If \( x \) had been a \texttt{val} rather than a \texttt{var}, the previous example would not be allowed.

Unfortunately, a completely accurate definition of “definitely assigned” or “definitely unassigned” is undecidable – impossible for the compiler to determine. So, X10 takes a conservative approximation of these concepts. If X10’s definition says that \( x \) is definitely assigned (or definitely unassigned), then it will be assigned (or not assigned) in every execution of the program.

However, there are programs which X10’s algorithm says are incorrect, but which actually would behave properly if they were executed. In the following example, \texttt{flag} is either \texttt{true} or \texttt{false}, and in either case \( x \) will be initialized. However, X10’s analysis does not understand this — thought it would understand if the example were coded with an \texttt{if-else} rather than a pair of \texttt{ifs}. So, after the two \texttt{if} statements, \( x \) is not definitely assigned, and thus the \texttt{assert} statement, which reads it, is forbidden.

\begin{verbatim}
def example(flag:Boolean) {
  var x : Long;
  if (flag) x = 1;
  if (!flag) x = 2;
  // ERROR: assert x < 3;
}
\end{verbatim}

19.1 Asynchronous Definite Assignment

Local variables and instance fields allow asynchronous assignment. A local variable can be assigned in an \texttt{async} statement, and, when the \texttt{async} is \texttt{finished}, the variable is definitely assigned.

\textbf{Example:}

\begin{verbatim}
val a : Long;
finish {
  async {
    \texttt{\cdots}
  }
  \texttt{\cdots}
}\end{verbatim}
19.2. CHARACTERISTICS OF DEFINITE ASSIGNMENT

This concept supports a core X10 programming idiom. A val variable may be initialized asynchronously, thereby providing a means for returning a value from an async to be used after the enclosing finish.

19.2 Characteristics of Definite Assignment

The properties “definitely assigned”, “singly assigned”, and “definitely unassigned” are computed by a conservative approximation of X10’s evaluation rules.

The precise details are up to the implementation. Many basic cases must be handled accurately; e.g., x=1; definitely and singly assigns x.

However, in more complicated cases, a conforming X10 may mark as invalid some code which, when executed, would actually be correct. For example, the following program fragment will always result in x being definitely and singly assigned:

```x
val x : Long;
var b : Boolean = mysterious();
if (b) x = cryptic();
if (!b) x = unknown();
```

However, most conservative approximations of program execution won’t mark x as properly initialized, though it is. For x to be properly initialized, precisely one of the two assignments to x must be executed. If b were true initially, it would still be true after the call to cryptic() — since methods cannot modify their caller’s local variables — and so the first but not the second assignment would happen. If b were false initially, it would still be false when !b is tested, and so the second but not the first assignment would happen. Either way, x is definitely and singly assigned.

However, for a slightly different program, this analysis would be wrong. E.g., if b were a field of this rather than a local variable, cryptic() could change b; if b were true initially, both assignments might happen, which is incorrect for a val.

This sort of reasoning is beyond most conservative approximation algorithms. Indeed, many do not bother checking that !b late in the program is the opposite of b earlier.) Algorithms that pay attention to such details and subtleties tend to be fairly expensive, which would lead to very slow compilation for X10 – for the sake of obscure cases.

X10’s analysis provides at least the following guarantees. We describe them in terms of a statement S performing some collection of possible numbers of assignments to
variables — on a scale of “0”, “1”, and “many”. For example, if (b) x=1; else 
{x=1; x=2; y=2;} might assign to x one or many times, and might assign to y zero or 
one time. Hence, after it, x is definitely assigned and may be multiply assigned, and y 
is neither definitely assigned nor definitely unassigned.

These descriptions are combined in natural ways. For example, if R says that x will be 
assigned 0 or 1 times, and S says it will be assigned precisely once, then R;S will assign 
it one or many times. If only one or R or S will occur, as from if (b) R; else S;, 
then x may be assigned 0 or 1 times.

This information is sufficient for the tests X10 makes. If x can is assigned one or many 
times in S, it is definitely assigned. It is an error if x is ever read at a point where it 
have been assigned zero times. It is an error if a val may be assigned many times.

We do not guarantee that any particular X10 compiler uses this algorithm; indeed, as
of the time of writing, the X10 compiler uses a somewhat more precise one. However, 
your conformant X10 compiler must provide results which are at least as accurate as 
this analysis.

Assignment: \( x = e \)

\( x = e \) assigns to x, in addition to whatever assignments \( e \) makes. For example, if 
\( \text{this.setX}(y) \) sets a field x to y and returns y, then \( x = \text{this.setX}(y) \) definitely 
and multiply assigns x.

async and finish

By itself, async \( S \) provides few guarantees. After an activity executes async\{x=1;\} 
we know that there is a separate activity which (on being scheduled) will set x to 1. We 
do not know that this has happened yet.

However, if there is a finish around the async, the situation is clearer. After finish 
async x=1;. x has definitely been assigned.

In general, if an async \( S \) appears in the body of a finish in a way that guarantees 
that it will be executed, then, after the finish, the assignments made by \( S \) will have 
occurred. For example, if \( S \) definitely assigns to x, and the body of the finish guaran-
tees that async \( S \) will be executed, then finish\{...async \( S \)...\} definitely assigns x.

if and switch

When if(E) S else T finishes, it will have performed the assignments of E, together 
with those of either S or T but not both. For example, if (b) x=1; else x=2; 
definitely assigns x, but if (b) x=1; does not.

switch is more complex, but follows the same principles as if. For example, switch(E){case 
1: A; break; case 2: B; default: C;} performs the assignments of E, and those
of precisely one of A, or B;C, or C. Note that case 2 falls through to the default case, so it performs the same assignments as B;C.

**Sequencing**

When R;S finishes, it will have performed the assignments of R and those of S, if R and S terminate normally. If R terminates abruptly, then only the assignments of R executed till the point of termination will have been executed. If R terminates normally, but S terminates abruptly then the assignments of R will have been executed and those of S executed till the point of termination.

For example, x=1;y=2; definitely assigns x and y, and x=1;x=2; multiply assigns x.

**Loops**

while(E)S performs the assignments of E one or more times, and those of S zero or more times. For example, if while(b()){x=1;} might assign to x zero, one, or many times. do S while(E) performs the assignments of E one or more times, and those of S one or more times.

for(A;B;C)D performs the assignments of A once, those of B one or more times, and those of C and D one or more times. for(x in E)S performs the assignments of E once and those of S zero or more times.

Loops are of very little value for providing definite assignments, since X10 does not in general know how many times they will be executed.

continue and break inside of a loop are hard to describe in simple terms. They may be conservatively assumed to cause the loop to give no information about the variables assigned inside of it. For example, the analysis may conservatively conclude that do{ x = 1; if (true) break; } while(true) may assign to x zero, one, or many times, overlooking the more precise fact that it is assigned once.

**Method Calls**

A method call E.m(A,B) performs the assignments of E, A, and B once each, and also those of m. This implies that X10 must be aware of the possible assignments performed by each method.

If X10 has complete information about m (as when m is a private or final method), this is straightforward. When such information is fundamentally impossible to acquire, as when m is a non-final method invocation, X10 has no choice but to assume that m might do anything that a method can do. (For this reason, the only methods that can be called from within a constructor on a raw – incompletely-constructed – object) are the private and final ones.)

- m cannot assign to local variables of the caller; methods have no such power.
• Let \( m \) be an instance method. \( m \) can assign to \( \text{var} \) fields of \textit{this} freely.

• Let \( m \) be an instance method. \( m \) cannot initialize \( \text{val} \) fields of \textit{this}. (But see §8.5.2 when one constructor calls another as the first statement of its body, the other constructor can initialize \( \text{vval} \) fields. This is a constructor call, not a method call.)

Recall that every container must be fully initialized upon exit from its constructor. X10 places certain restrictions on which methods can be called from a constructor; see §8.11.1. One of these restrictions is that methods called before object initialization is complete must be \textit{final} or \textit{private} — and hence, available for static analysis. So, when checking field initialization, X10 will ensure:

1. Each \textit{val} field is initialized before it is read. A method that does not read a \textit{val} field \( f \) \textit{may} be called before \( f \) is initialized; a method that reads \( f \) must not be called until \( f \) is initialized. For example, a constructor may have the form:

   ```
   class C {
      val f : Long;
      val g : String;
      def this() {
         f = fless();
         g = useF();
      }
      private def fless() = "f not used here".length();
      private def useF() = "f=" + this.f;
   }
   ```

2. \textit{var} fields require a deeper analysis. Consider a \textit{var} field \( \text{var} \) \( x:T \) without initializer. If \( T \) has a default value, \( x \) may be read inside of a constructor before it is otherwise written, and it will have its default value.

   If \( T \) has no default value, an analysis like that used for \textit{vals} must be performed to determine that \( x \) is initialized before it is used. The situation is more complex than for \textit{vals}, however, because a method can assign to \( x \) as well read from it. The X10 compiler computes a conservative approximation of which methods read and write which \( \text{var} \) fields. (Doing this carefully requires finding a solution of a set of equations over sets of variables, with each callable method having equations describing what it reads and writes.)

\texttt{at(p)S} performs precisely the assignments of \( p \) and those of \( S \). Note that \( S \) is executed at the place named by \( p \) in an environment in which all variables used in \( S \) but defined outside \( S \) are bound to copies (made at \( p \)) of the values they had at the \texttt{at(p)S} statement (§13.3).
atomic

atomic S performs the assignments of S, and when(E)S performs those of E and S. Note that E or S may terminate abruptly.

try

try S catch(x:T1) E1 ... catch(x:Tn) En finally F performs some or all of the assignments of S, plus all the assignments of zero or one of the E’s, plus those of F. For example,

```
try {
  x = boomy();
  x = 0;
}
catch(e:Boom) { y = 1; }
finally { z = 1; }
```

assigns x zero, one, or many times, assigns y zero or one time, and assigns z exactly once.

Expression Statements

Expression statements E; and other statements that execute an expression and do something innocuous with it (local variable declaration and assert) have the same effects as E.

return, throw

Statements that do not finish normally, such as return and throw, do not initialize anything (though the computation of the return or thrown value may). They also terminate a line of computation. For example, if(b) {x=1; return;} x=2; definitely and singly assigns x.

---

1 A more precise analysis could discover that x cannot be initialized only once.

A Deprecations

X10 version 2.4 has a few relics of previous versions, code that is being used by libraries but is not intended for general programming. They should be ignored.

These are:

- acc variables.
- The offers clause for use with collecting finish.
- The grammar allows covariant and contravariant type parameters, marked by + and -:

  ```
  class Variant[X, +Y, -Z] {}
  ```

  X10 does not support these in any other way.
- The syntax allows for a few Java-isms, such as c.class and super.class, which are not used.
B  Change Log

B.1  Changes from X10 v2.5

To resolve parsing ambiguities, the property keyword is now mandatory to introduce property methods.

The X10 language now supports trailing closures. A trailing closure is a closure block that is written and after the parentheses of a function call. This closure block is passed as a closure without argument to the function.

B.2  Changes from X10 v2.4

Although there were no backwards incompatible language changes between X10 v2.4 and X10 v2.5, a few core class library APIs did have backwards incompatible changes. These changes were driven by our experience with Resilient and Elastic X10 and are designed to better support X10 computations over a dynamically varying number of Places. In summary,

1. Static constants such as PlaceGroup.WORLD, and Place.MAX\_PLACES were removed. They are replaced by Place.places() and Place.numPlaces() which return values that represent the current view on the dynamically changeable set of Places available to the computation.

2. The removal of iteration functionality (next and prev) from Place. This functionality is now provided only through PlaceGroup.

3. The addition of PlaceTopology to provide a more flexible set of APIs describing the topological relationships of Places.

In addition, the put and get methods of x10.util.Map were changed to no longer wrap their return value in an instance of x10.util.Box. This improves the common case efficiency of map usage, but does require that the Values stored in Map satisfy the haszero constraint.
B.3 Changes from X10 v2.3

X10 v2.4 is not backwards compatible with X10 v2.3. The motivation for making backwards incompatible language changes with this release of X10 is to significantly improve the ability of the X10 programmer to exploit the expanded memory capabilities of modern computer systems. In particular, X10 v2.4 includes an extensive redesign of arrays and a change of the default type of unqualified integral literals (e.g., 2) from Int to Long. Taken together these two changes enable natural exploitation of large memories via 64-bit addressing and Long-based indexing of arrays and similar data structures.

B.3.1 Integral Literals

The default type of unqualified integral literals was changed from Int to Long.

The qualifying suffix n and un are used to indicate Int and UInt literals respectively. The suffix u is now interpreted as indicating a ULong literal.

B.3.2 Arrays

An extensive redesign of the X10 abstractions for arrays is the major new feature of the X10 v2.4 release. Although this redesign only involved very minor changes to the actual X10 language specification, the core class libraries did change significantly. As mentioned above, the driving motivation for the change was a long-contemplated strategic decision to shift to from Int-based (32-bit) to Long-based (64-bit) indexing for all X10 arrays. This change enables X10 to better utilize the rapidly expanding memory capacity and 64-bit address space found on modern machines. For consistency, the id field of x10.lang.Place and the size and indexing-related APIs of the x10.util collection hierarchy were also changed from Int to Long.

Once this inherently backwards-incompatible decision was made, the X10 team decided to do a larger rethinking of all of X10's array implementations to introduce a new time and space optimal implementation of zero-based, dense, rectangular multi-dimensional arrays. This new implementation, in the x10.array package, is intended to provide the best possible performance for the common-case it supports. The previous, more general array implementation is still available, but has been relocated to a new package x10.array.regionarray. In addition, the x10.lang.Rail class was re-introduced as a separate class in its own right and provides the intrinsic indexed storage abstraction on which both array packages are built. The intent is that the combination of Rail, x10.array and x10.regionarray provide a spectrum of array abstractions that capture common usage patterns and enable appropriate trade-offs between performance and flexibility.

In more detail the major array-related changes made in the X10 v2.4 release are
1. The class `x10.lang.Rail` was introduced. It provides an efficient one-dimensional, zero-based, densely indexed array implementation. Rail will provide the best performance and is the preferred implementation of this basic abstraction.

2. The array literal syntax `[1,2,3]` is now defined to create a Rail instead of an Array.

3. The main method signature is changed from `Array[String]` to `Rail[String].

4. `x10.util.IndexedMemoryChunk` has removed from the X10 standard library.

5. To enable usage of classes from both `x10.array` and `x10.regionarray`, the package `x10.array` is no longer auto-imported by the X10 compiler.

6. Most classes in the `x10.array` package in the X10 v2.3 release were relocated to the `x10.regionarray` package in v2.4. A few classes like `Point` and `PlaceGroup` were moved to the `x10.lang` package instead.

7. `Point`, `Region`, `Dist`, etc. were all updated to support long-based indexing by consistently changing indexing related fields and methods from `Int` to `Long`.

### B.3.3 Other Changes from X10 v2.3

1. The custom serialization protocol was changed to operate in terms of new user-level classes `x10.io.Serializer` and `x10.io.Deserializer`. The `serialize` method of the `xcd10.io.CustomSerialization` interface now takes a `Serializer` as an argument. The custom deserialization constructor for a class takes a `Deserializer`.

2. The `x10.io.SerialData` class used by the X10 v2.3 custom serialization protocol has been removed from the class library.

3. A constraint was added to `PlaceLocalHandle` that types used to instantiate a `PlaceLocalHandle` must satisfy both the `isref` and `haszero` constraints.

4. The `x10.util.Team` API was revised by (a) removing the endpoint argument from all API calls and (b) to operate on `Rail` and `xcd’Long’ where appropriate.

### B.4 Changes from X10 v2.2

1. In previous versions of X10 static fields were eagerly initialized in `Place 0` and the resulting values were serialized to all other places before execution of the user main function was started. Starting with X10 v2.2.3, static fields are lazily initialized on a per-Place basis when the field is first read by an activity executing in a given Place.

2. The new syntax `T isref` for some type `T` will hold if `T` is represented by a pointer at runtime. This is similar to the type constraint `T haszero`. `T isref` is true for `T` that are function types, classes, and all values that have been cast to
interfaces (including boxed structs). \( T \text{ isref} \) is used in the standard library, e.g. for the \texttt{GlobalRef}[T] and \texttt{PlaceLocalHandle}[T] APIs.

3. \texttt{x10.lang.Object} is gone, there is now no single class that is the root of the X10 class hierarchy.
   - If, for some reason, you were explicitly extending \texttt{Object}, don’t do that anymore.
   - If you were doing \texttt{new Object()} to get a fresh value, use \texttt{new Empty()} instead.
   - If you were using \texttt{Object} as a supertype, use \texttt{Any} (the one true supertype).
   - If you were using the type constraint \( T <: \texttt{Object} \) to disallow structs, use \( T \text{ isref} \) instead.

4. The exception hierarchy has changed, and checked exceptions have been reintroduced. The ‘throws’ annotation is required on methods, as in Java. It is not supported on closures, so checked exceptions cannot be thrown from a closure. The exception hierarchy has been chosen to exist in a 1:1 relationship with Java’s. However, unlike Java, we prefer using unchecked exceptions wherever possible, and this is reflected in the naming of the X10 classes. The following classes are all in the \texttt{x10.lang} package.
   - \texttt{CheckedThrowable} (mapped to \texttt{java.lang.Throwable})
   - \texttt{CheckedException} extends \texttt{CheckedThrowable} (mapped to \texttt{java.lang.Exception})
   - \texttt{Exception} extends \texttt{CheckedException} (mapped to \texttt{java.lang.RuntimeException})
   - \texttt{Error} extends \texttt{CheckedThrowable} (mapped to \texttt{java.lang.Error})

Anything under \texttt{CheckedThrowable} can be thrown using the \texttt{throw} statement. But anything that is not under \texttt{Exception} or \texttt{Error} can only be thrown if it is caught by an enclosing \texttt{try/catch}, or it is thrown from a method with an appropriate \texttt{throws} annotation, as in Java.

\texttt{RuntimeException} is gone from X10. Use \texttt{Exception} instead.

All the exceptions in the standard library are under \texttt{Exception}, except \texttt{AssertionError} and \texttt{OutOfMemoryException}, which are under \texttt{Error} (as in Java). This means all exceptions in the standard library remain unchecked.

### B.5 Changes from X10 v2.1

1. Covariance and contravariance are gone.

2. Operator definitions are regularized. A number of new operator symbols are available.

3. The operator \texttt{in} is gone. \texttt{in} is now only a keyword.
4. Method functions and operator functions are gone.

5. m..n is now a type of struct called IntRange.

6. for(i in m..n) now works. The old forms, for((i) in m..n) and for([i] in m..n), are no longer needed.

7. (e as T) now has type T. (It used to have an identity constraint conjoined in.)

8. vars can no longer be assigned in their place of origin. Use a GlobalRef[Cell[T]] instead. We'll have a new idiom for this in 2.3.

9. The -STATIC_CALLS command-line flag is now -STATIC_CHECKS.

10. Any string may be written in backquotes to make an identifier: `while`.

11. The next and resume keywords are gone; they have been replaced by static methods on Clock.

12. The typed array construction syntax new Array[T][t1,t2] is gone. Use [t1 as T, t2] (if just plain [t1,t2] doesn’t work).

### B.6 Changes from X10 v2.0.6

This document summarizes the main changes between X10 2.0.6 and X10 2.1. The descriptions are intended to be suggestive rather than definitive; see the language specification for full details.

#### B.6.1 Object Model

1. Objects are now local rather than global.

   (a) The home property is gone.

   (b) at(P)S produces deep copies of all objects reachable from lexically exposed variables in S when it executes S. (Warning: They are copied even in at(here)S.)

2. The GlobalRef[T] struct is the only way to produce or manipulate cross-place references.

   (a) GlobalRef’s have a home property.

   (b) Use GlobalRef[Foo](foo) to make a new global reference.

   (c) Use myGlobalRef() to access the object referenced; this requires here == myGlobalRef.home.

3. The ! type modifier is no longer needed or present.
4. **global** modifiers are now gone:

   (a) **global** methods in *interfaces* are now the default.

   (b) **global** *fields* are gone. In some cases object copying will produce the
       same effect as global fields. In other cases code must be rewritten. It may
       be desirable to mark nonglobal fields **transient** in many cases.

   (c) **global** *methods* are now marked @Global instead. Methods intended to
       be non-global may be marked @Pinned.

### B.6.2 Constructors

1. **proto** types are gone.

2. Constructors and the methods they call must satisfy a number of static checks.

   (a) Constructors can only invoke **private** or **final** methods, or methods an-
       notated @NonEscaping.

   (b) Methods invoked by constructors cannot read fields before they are written.

   (c) The compiler ensures this with a detailed protocol.

3. It is still impossible for X10 constructors to leak references to **this** or observe
   uninitialized fields of an object. Now, however, the mechanisms enforcing this
   are less obtrusive than in 2.0.6; the burden is largely on the compiler, not the
   programmer.

### B.6.3 Implicit clocks for each finish

Most clock operations can be accomplished using the new implicit clocks.

1. A **finish** may be qualified with **clocked**, which gives it a clock.

2. An **async** in a **clocked finish** may be marked **clocked**. This registers it on
   the same clock as the enclosing **finish**.

3. **clocked async** $S$ and **clocked finish** $S$ may use **next** in the body of $S$ to
   advance the clock.

4. When the body of a **clocked finish** completes, the **clocked finish** is dropped
   from the clock. It will still wait for spawned asyncs to terminate, but such asyncs
   need to wait for it.
B.6.4 Asynchronous initialization of val

vals can be initialized asynchronously. As always with vals, they can only be read after it is guaranteed that they have been initialized. For example, both of the prints below are good. However, the commented-out print in the async is bad, since it is possible that it will be executed before the initialization of a.

```scala
val a:Int;
finish {
    async {
        a = 1;
        print("a=" + a);
    }
    // WRONG: print("a=" + a);
}
print("a=" + a);
```

B.6.5 Main Method

The signature for the main method is now:

```scala
def main(Array[String]) {...}
```
or, if the arguments are actually used,

```scala
def main(argv: Array[String](1)) {...}
```

B.6.6 Assorted Changes

1. The syntax for destructuring a point now uses brackets rather than braces: for(
   [i] in 1..10 ), rather than the prior (i).

B.6.7 Safety of atomic and when blocks

1. Static effect annotations (safe, sequential, nonblocking, pinned) are no longer used. They have been replaced by dynamic checks.

2. Using an inappropriate operation in the scope of an atomic or when construct will throw IllegalOperationException. The following are inappropriate:
   - when
   - resume() or next on clocks
   - async
   - Future.make(), or Future.force().
   - at
B.6.8 Removed Topics

The following are gone:

1. `foreach` is gone.
2. All vars are effectively shared, so `shared` is gone.
3. The place clause on `async` is gone. `async (P) S` should be written `at(P) async S`.
4. Checked exceptions are gone.
5. `future` is gone.
6. `await ... or ...` is gone.
7. `const` is gone.

B.6.9 Deprecated

The following constructs are still available, but are likely to be replaced in a future version:

1. `ValRail`.
2. `Rail`.
3. `ateach`.
4. `offers`. The `offers` concept was experimental in 2.1, but was determined inadequate. It has not been removed from the compiler yet, but it will be soon. In the meantime, traces of it are still visible in the grammar. They should not be used and can safely be ignored.

B.7 Changes from X10 v2.0

Some of these changes have been made obsolete in X10 2.2.

- Any is now the top of the type hierarchy (every object, struct and function has a type that is a subtype of Any). Any defines `home`, `at`, `toString`, `typeName`, `equals` and `hashCode`. Any also defines the methods of `Equals`, so `Equals` is not needed any more.
- Revised discussion of incomplete types.
- The manual has been revised and brought into line with the current implementation.
B.8 Changes from X10 v1.7

The language has changed in the following ways. Some of these changes have been made obsolete in X10 2.2.

- **Type system changes**: There are now three kinds of entities in an X10 computation: objects, structs and functions. Their associated types are class types, struct types and function types.

  Class and struct types are called *container types* in that they specify a collection of fields and methods. Container types have a name and a signature (the collection of members accessible on that type). Collection types support primitive equality `==` and may support user-defined equality if they implement the `x10.lang.Equals` interface.

  Container types (and interface types) may be further qualified with constraints.

  A function type specifies a set of arguments and their type, the result type, and (optionally) a guard. A function application type-checks if the arguments are of the given type and the guard is satisfied, and the return value is of the given type.

  A function type does not permit `==` checks. Closure literals create instances of the corresponding function type.

  Container types may implement interfaces and zero or more function types.

  All types support a basic set of operations that return a string representation, a type name, and specify the home place of the entity.

  The type system is not unitary. However, any type may be used to instantiate a generic type.

  There is no longer any notion of value classes. value classes must be re-written into structs or (reference) classes.

- **Global object model**: Objects are instances of classes. Each object is associated with a globally unique identifier. Two objects are considered identical `==` if their ids are identical. Classes may specify global fields and methods. These can be accessed at any place. (global fields must be immutable.)

- **Proto types**: For the decidability of dependent type checking it is necessary that the property graph is acyclic. This is ensured by enforcing rules on the leakage of this in constructors. The rules are flexible enough to permit cycles to be created with normal fields, but not with properties.

- **Place types**: Place types are now implemented. This means that non-global methods can be invoked on a variable, only if the variable’s type is either a struct type or a function type, or a class type whose constraint specifies that the object is located in the current place.

  There is still no support for statically checking array access bounds, or performing place checks on array accesses.
C  Options

C.1  Compiler Options: Common

The X10 compilers have many useful options.

C.1.1  Optimization: -O or -optimize

This flag causes the compiler to generate optimized code.

C.1.2  Debugging: -DEBUG=boolean

This flag, if true, causes the compiler to generate debugging information. It is false by default.

C.1.3  Call Style: -STATIC_CHECKS, -VERBOSE_CHECKS

By default, if a method call could be correct but is not necessarily correct, the X10 compiler generates a dynamic check to ensure that it is correct before it is performed. For example, the following code:

    def use(n:Int{self == 0}) {}  
    def test(x:Int) {  
        use(x); // creates a dynamic cast  
    }

compiles even though it is possible that x! = 0 when use(x) is called. In this case, the compiler inserts a cast, which has the effect of checking that the call is correct before it happens:

    def use(n:Int{self == 0}) {}  
    def test(x:Int) {  
        use(x as Int{self == 0});  
    }
The compiler produces a warning that it inserted some dynamic casts. If you then want to see what it did, use `-VERBOSE_CHECKS`.

You may also turn on strict static checking, with the `-STATIC_CHECKS` flag. With static checking, calls that cannot be proved correct statically will be marked as errors.

**C.1.4 Help: -help and --help**

These options cause the compiler to print a list of all command-line options.

**C.1.5 Source Path: -sourcepath path**

This option tells the compiler where to look for X10 source code.

**C.1.6 Output Directory: -d directory**

This option tells the compiler to produce its output files in the specified directory.

**C.1.7 Executable File: -o path**

This option tells the compiler what path to use for the executable file.

**C.2 Compiler Option: C++**

The C++ compilation command `x10c++` has the following option as well.

**C.2.1 Runtime: -x10rt impl**

This option tells which runtime implementation to use. The choices are sockets, standalone, pami, mpi, and bgas_bgp.

**C.3 Compiler Option: Java**

The Java compilation command `x10c` has the following option as well.

**C.3.1 Class Path: -classpath path**

This option is used in conjunction with the Java interoperability feature to tell the compiler where to look for Java .class files that may be used by the X10 code being compiled.
C.4 Execution Options: Java

The Java execution command `x10` has a number of options as well.

C.4.1 Class Path: `-classpath path`

This option specifies the search path for class files.

C.4.2 Library Path: `-libpath path`

This option specifies the search path for native libraries.

C.4.3 Heap Size: `-mssize` and `-mxsize`

Sets the minimum and maximum size of the heap.

C.4.4 Stack Size: `-sssize`

Sets the maximum size of the stack.

C.4.5 Places: `-np count`

Specify the number of places.

C.4.6 Hosts: `-host host1,host2,...` or `-hostfile file`

Specify the hosts either by the list of host names or the host file.

C.4.7 Runtime: `-x10rt impl`

This option tells which runtime implementation to use. The choices are `sockets`, `JavaSockets` (experimental), and `mpi` (experimental).

C.4.8 Help: `-h`

Prints a listing of all execution options.
C.5 Running X10

An X10 application is launched either by a direct invocation of the generated executable or using a launcher command. The specification of the number of places and the mapping from places to hosts is transport specific and discussed in §C.6 for Managed X10 (Java back end) and §C.7 for Native X10 (C++ back end). For distributed runs, the x10 distribution (libraries) and the compiled application code (binary or bytecode) are expected to be available at the same paths on all the nodes.

Detailed, up-to-date documentation may be found at [http://x10-lang.org/documentation/practical-x10-programming/x10rt-implementations.html](http://x10-lang.org/documentation/practical-x10-programming/x10rt-implementations.html)

C.6 Managed X10

Managed X10 applications are launched using the x10 script followed by the qualified name of the main class.

```
x10c>HelloWholeWorld.x10
x10 HelloWholeWorld
```

The main purpose of the x10 script is to set the jvm classpath and the `java.library.path` system property to ensure the x10 libraries are on the path.

C.7 Native X10

On most platforms and for most transports, X10 applications can be launched by invoking the generated executable.

```
x10c++ -o HelloWholeWorld HelloWholeWorld.x10
./HelloWholeWorld
```

On cygwin, X10 applications must be launched using the runx10 script followed by the name of the generated executable.

```
x10c++ -o HelloWholeWorld HelloWholeWorld.x10
runx10 HelloWholeWorld
```

The purpose of the runx10 script is to ensure the x10 libraries are on the path.
Acknowledgments and Trademarks

The X10 language has been developed as part of the IBM PERCS Project, which is supported in part by the Defense Advanced Research Projects Agency (DARPA) under contract No. NBCH30390004.
